2. There is a vagueness in your description: "the varnish," what kind? However, any varnish degrades the brilliancy to some extent. The best mode of proceeding is, in our opinion, to pour on the positive picture, *after* its final washing, some dilute albumen (say white of egg one part, water seven parts), drain and dry. When dry, dip into your iron solution to coagulate the albumen, and again wash and dry. We do not think the cause assigned by you as conducing to the degradation of tone the correct one, but that it is rather due to an interference with the reflecting surfaces of the molecules of silver. The brilliancy obtained by nitric acid is apt to be deficient in half-tone from the particles of reduced silver being much larger than when a less energetic oxidising agent is employed, the metallic glare is also liable to be offensive. An alkaline bath generally produces fogging, properly so called; what you describe is rather due to organic matter in excess.—Ed.]

A GOOD IDEA.

To the Editor.

Sir,—In the present dearth of photographic news, the following incident may be interesting.

While taking a picture in Highgate Cemetery a short time since, a man who was digging a grave close by laid down his spade and came to watch proceedings. On his making some inquiries, and showing some knowledge of the art, I ascertained that he and a mate of his, instead of spending their money in beershops, saved it up, bought a set of apparatus, and fitted up one of the catacombs for a dark room. Whenever a monument of any importance is erected, they photograph it when work is over, and take the copy to the owner of the original, whose address is of course ascertainable, and in nine cases out of ten they obtain five shillings or so for their work, thus making a nice addition to their weekly receipts.

A CORRESPONDENT.

COLLODIO-ALBUMEN.

To the Editor.

Sir,—As I have been a reader of your Journal for years, and have never before asked a favour, I shall be very glad of a little of your kind information, especially if it appear in your next.—I am, yours, &c.

M. C. C.

1. Will it signify if I strengthen my collodio-albumen silver bath with *crystallised* nitrate of silver, the bath having been made with *fused* nitrate?

2. What are the appearances of a plate prepared as above by the collodio-albumen process when too much iodide of ammonium has been added, and what when too little?

3. What will be the result if too much glacial acetic acid has been added to the silver bath? I use the same for collodion and albumen.

4. Plates which have been prepared three weeks or so, generally turn of a coffee colour after being about half developed. Is there any remedy, and what?

5. I get some beautiful negatives of near objects, such as doorways, &c., but when I go further back to take a tower, or *a large sized object*, say one hundred yards off, I often get a very indistinct picture, *focussing as fine as possible*. I think it is owing to a too bright sky, though my back is to the sun. Your opinion.

6. I have some negatives, fetched many miles *(stereo)*, which look every thing I wish, but thin, both sky and subject, taken in very dull weather, looks reddish; fixed in hypo. Can I now strengthen them by another development? Would they have been better had I used more nitrate of silver in developing, or is my bath too weak?

7. Do you think it best to develop as far as until all detail is visible before adding silver to the developer, or use it with first dose at commencement?

[We presume that the whole of the preceding queries apply to the collodio-albumen process.

1. No objection.

2. Rather indefinitely put. Too much iodide in the bath, the collodion, or the albumen. If the bath be super-saturated, a reduction of temperature would cause multitudes of spots. If in the collodion, the excited film would be very dense and creamy in appearance, and parts might come off in flakes. If in the albumen, it is apt to form small crystals in drying.

3. It would render the film slow to receive the impression in the camera, and when obtained would probably be weak.

4. When you say *prepared* three weeks, do you mean *excited* three weeks? If so, it may arise from insufficient washing after the sensitising bath, or from some slight exposure to light. Remedy—Wash very thoroughly, and in developing use more silver solution.

5. You probably use too large an aperture to your lens; put in a diaphragm with an aperture only half the diameter you now employ.

6. The weakness may be from over-exposure, or from too much free acid, and too little silver when developing. You may be able to intensify even now by redevelopment.

7. Decidedly add the silver at once to your developing solution, unless your negatives have been much over-exposed.—Ed.]

CAPABILITIES OF PROFESSOR PETZVAL'S LENS.

To the Editor.

Sir,—I have read the description of Mr. Rejlander's picture, *The Wayfarer*, in your Journal, and I perfectly agree with your opinion. Since that time I have received from Mr. Rejlander the companion to this picture, 14 × 12 inches, a female figure sitting, surrounded with domestic furniture, having some needlework in hand, but occupied with some meditation. Most probably you too will also receive a copy of this picture. I consider it still superior in comparison with the first. But you yourself are certainly the best judge.

My object in addressing you, is to state that both pictures are taken by the original Petzval lens (3 inch diam.), and I think they are almost the first specimens of an application of this lens for a kind of portraiture.

I will certainly not diminish the due merits of Mr. Rejlander; on the contrary, I will join with great pleasure in the compliments due to him for the attention, skill, and artistic feeling demonstrated in this picture. But I think it would be only reasonable to mention anywhere to the public the fact, that they have been taken by this lens. Professor Petzval has been so abused for his hard labour, and his instruments have been run down in such an ugly manner, other colours put on the truth, that I could only consider it justice to mention the above stated fact.

I am, yours, &c. PAUL PRETSCH.

162, *Great Portland Street, W.*

VARNISH.—DRY COLLODION.

To the Editor.

Sir,—I should feel much obliged if you would enlighten me upon the following points:—

1st. I tried to make some transparent varnish after the recipe given in your number of the 1st June, in the letter to "Eusebius," but could not succeed. I broke the lac into small pieces and pounded it in a mortar, and afterwards dried it in an oven, but it would not dissolve in the alcohol; it was white lac in sticks, such as the small piece enclosed.

2nd. In the formula for Mr. Maxwell Lyte's toning bath, it is said that the portion used must not be returned to the stock bottle. Can it then only be used once? If so, it must be rather expensive.

3rd. Dr. Norris's plates are spoken of in the Dry Collodion Company's advertisements as *patent.* Does this preclude amateurs from preparing them for themselves?

4th. Where can I obtain a good description of Dr. Norris's process?

Hoping that you will excuse the trouble I am causing you,

I am, yours, &c., Z.

Liverpool, August 23, 1859.

[1. It may require the aid of heat to dissolve the lac, and perhaps your alcohol is too weak. Take the cork out of the bottle, and tie over the neck a piece of wetted bladder, and set the bottle in the sunshine, or in a warm place for a few days; or place the bottle in warm water for a few hours, shaking occasionally.

2. It can only be used once; but it is not expensive, inasmuch as if the number of prints to be toned be small, you may take a sufficient quantity of the normal bath to do the work, and *expand its bulk* by the addition of water sufficient to allow of easy manipulation.

3. Amateurs may make their own dry plates, and use them too.

4. In our last volume.—Ed.]

WOODWARD'S SOLAR CAMERA.

To the Editor.

Sir,—My attention has been called to a letter from Mr. Atkinson in your last number, having appended to it a note from yourself, referring to back numbers of the *Journal of the Photographic Society* as containing a description of apparatus for enlarging small positives.

You state in the note appended to Mr. Atkinson's letter that you see nothing new in the solar camera, much less ground for a patent, and refer to the process of Mr. Wenham, and also your own, as published in certain back numbers of the above journal.

Now, I am perfectly familiar with your process as published, also that of Mr. Wenham, and respectfully beg leave to say that neither of them bear any resemblance to the solar camera.

As I am about to leave England for my home, I have written this in order that the impression created by your remarks already alluded to may be removed.

I would beg you to call on Mr. Kilburn, or some one having a solar camera, and examine it while exposed to the rays of the sun. If you do this, I feel satisfied that you will take pleasure not only in making the correction I desire, but in advocating the use of the solar camera throughout England.—I am, yours, &c. D. A. WOODWARD.

Liverpool, August 26, 1859.

[We have within the last few days paid a visit to Mr. Kilburn's studio and seen the solar camera in operation, as also some of its results. We regret that we have to affirm our former statement—the results are not any better than those produced several years back by Mr. Wenham, nor does the solar camera involve any novelty of principle whatever. We shall probably have something to say upon the subject in a future number. —Ed.]

ANSWERS TO CORRESPONDENTS.

G. Jones (Guildford)—We have forwarded the packages as requested.

J. F. White.—We have nothing *new* ready, and no time to prepare anything just now, being *very* busy.

W. E. J., Back Creek, Amherst, Victoria.—A parcel containing what you wished for has been despatched. There is now no agent in this country that we know of for the Journal you name.

Inexperience.—5, 4, 3 are the only *first*-class makers; we prefer them in the order named. 8 is not a maker at all; the remainder are much on a level, but *a long way* below the others for the *kind* you name.

A Bewildered One.—You are not singular. Read the article on "Experiments in Parallel Directions," in the present number, and take comfort from our still greater misfortune.

J. R.—The quarter plate portrait combination you have used is of *too long focus*, a smaller lens will produce a larger image as you require it. Your letter has arrived too late for an extended reply this time; as we have several matters in type that must wait for our next.

Laura and Jane M.—That "annoying Charles" must certainly be extinguished. Take wood naphtha and dissolve in it as much shellac as will bring it to the consistence of treacle. If you put into a bottle shellac, so as not quite to fill it a quarter of the way up, then fill with the pyroxylic spirit, it will about be the thing. Or the cement, known as *liquid glue*, purchaseable at from threepence to sixpence per bottle, will answer the same purpose.

A. K. S.—To transfer positives to japanned leather, add three drops of nitric acid to one ounce of alcohol. Pour a sufficiency of the above on to the collodion and off again, then, while still damp, press the leather in close contact, taking care to remove all air bubbles; when dry the whole can be removed from the glass. Black varnished paper may be treated in the same way. The lenses you name are as far superior to that you speak of already possessing as gold is to silver; there is no comparison between them.

T. Markham, R. C., and Albumen—You had better try Mr. Sanford, of Red Lion Square, London. We believe he undertakes to prepare paper by any formula with which his customers please to furnish him:—of course at an extra charge if only a small quantity be required, owing to the impossibility of avoiding some waste of material; but probably if you require much it might answer his purpose without extra charge. We cannot undertake to make any such inquiries—you can do so at the cost of postage.

Φωτο.—We are not so arbitrary as *The Times*, nor is there any necessity for such precaution with us. Your mishap is a very trifling one. Filter the bath, and the reduced silver which will be left on the filter paper needs only washing to render it fit for being dissolved in nitric acid; the remainder of the bath will be fit for use after being rendered neutral, or nearly so, by the addition of a little carbonate of soda in solution. It will probably be a little acid from there being most likely some free acid in the developing solution added.

Robert Dart.—The explanation is simple enough; it is low-priced articles that dealers prefer to sell, as they can get a higher rate of profit on them and the demand is mostly in favour of the cheap, which commands a ready sale. The reply given is all nonsense. What you wrote for is for the best; you can *certainly* obtain it at Murray & Heath's, Piccadilly; Burfield & Rouch's, in the Strand; or at Knight & Co.'s, Foster Lane, Cheapside, and also at Brown's Medical Glass Warehouse, Farringdon Street, City. They are *not* cheap, but unquestionably good.

Querist.—1. Add half a grain of bromide of cadmium to each ounce of your collodion as now in use.—2. We do not advise an iron developer in *hot* weather; but, if used at all, say proto-sulphate of iron ten grains, water six drachms, Beaufoy's acetic acid two drachms.—3. We know nothing about the commercial aspect of photography; but perhaps Mr. Gladwell, Gracechurch Street, or Mr. Nottage, Cheapside, may assist you. —4. The index will be published at the conclusion of the volume, which is completed at the close of each year.—5. After six p.m. on most days, Thursdays being least certain.

T. Parkhouse.—You will find our report on Derogy's lenses in a recent number, from which, if you refer, you will perceive that Mr. Lloyd Chapman, in his advertisement, does not quote quite fairly. We did *not* state that they are "equal to six ordinary lenses," but that the labour of *testing one* of these was as great as that of trying six ordinary lenses. These lenses are good, and certainly very cheap; it is therefore to be regretted that any exaggerated statement should be made about them, a proceeding sure to bring them into discredit. We perceive, by the way, that the conductor of a contemporary publication has mistaken the application of the supplementary lenses when employed for landscape purposes. They should be attached in contact with, and in place of the diaphragm, the front of the portrait combination being removed to the back of the tube in all cases when employed for taking views, except when three pairs of lenses are in use at once.

*** Among several articles in type which are left over till our next, are Notices of Recently-published Stereographs and the Letter of our Australian Correspondent.

☞ *All* Editorial *Communications*, Books for Review, *&c., should be forwarded to the Editor*, GEORGE SHADBOLT, 2, *Upper Hornsey Rise, London, N.*

All Advertisements *and* Letters *on the* Business *of this* Journal, *should be addressed to the* Publisher, 32, *Castle Street, Liverpool.*

THE PHOTOGRAPHIC JOURNAL.

No. 102, Vol. VI.—SEPTEMBER 15, 1859.

In our last we had occasion to make some remarks in connection with a paper by * * * M.D., published in that number, and one by the same contributor previously given, but we may repeat here our conviction that there is, in our opinion, *no ground whatever* for the charge of plagiarism which has been brought against the author, whose name we are now permitted to disclose, as will be seen by a letter we publish amongst our correspondence, signed R. L. Maddox. Moreover, we consider the process last given by Dr. Maddox as one calculated to play an important part in photography, and regret that the pressing nature of other engagements precludes the possibility of our personally working at it at present. We trust however that we have been able to enlist the services of a very able amateur to test its value, in addition to those of its author.

We believe the original idea of employing albumenised paper as the basis for a negative is due to Mr. Mayall, it having been suggested by him in the very first year of the existence of the Photographic Society, but whether he ever carried it out into practice we are not aware. The superior keeping quality of waxed over simple calotype paper after excitation is an important consideration in the employment of the former, particularly as eventually the operation of waxing must be performed with both; and the persistence of the actinic impression, subsequent to the removal of the iodide of silver, when albumen has been used in conjunction with the silver salt, is a good reason for including this feature in negative processes if practicable. The very simple and efficient method of rendering the paper transparent, adopted by Dr. Maddox as a substitute for waxing, is another very troublesome obstacle removed; and, finally, the results obtained by this operator demonstrate clearly that the anticipatory calculations have been well designed. It is true that there are still some little difficulties of manipulation to be overcome before we may regard the process as perfect, but these are not such as to offer any great amount of apprehension about their removal.

The attempt to apply the albumen with the waxing and iodising solutions at one operation does not appear to have worked very satisfactorily, but we do not regard this as of any great moment, though it would have possibly been a convenience if practicable. It appears also that some difficulty exists with regard to floating the albumenised paper upon the sensitising bath, in consequence of its having a tendency to curl up very obstinately when wetted on one side only. It will therefore be preferable to immerse the sheet entirely; and though this would be objectionable to some extent with *un*albumenised paper, in consequence of its conducing to a development of the image in the fabric of the paper itself, rather than on its surface, thus giving rise to a want of distinctness of detail, yet with albumenised paper we scarcely imagine that the same effect would occur except in the high lights of the picture, where it would be of advantage, while the delicate shadows and semitones would, we have reason to believe, be confined strictly to the albumen, and consequently to the surface—a point of vital importance in determining the brilliancy of the resulting positive.

We find that difficulty also has been experienced in evenly coating the paper with albumen, and as we have had complaints from several correspondents relative to their inability to procure albumenised paper prepared by any formula except that adopted by the dealers, we may probably in our next, or in an early number, touch on the subject of preparing it.

We presume that the season for active photographic operations in the field may now be considered as past the meridian, although probably the majority of amateurs do not get their artillery into full play until thus near to the close of the engagement. We have, during the past twelve months, had so many contrivances brought to bear for working wet collodion out of doors, in the shape of tents, barrows, boxes, carriages, perambulators, *et hoc genus omne*, that it would be an interesting inquiry to ascertain at the close of the season what amount of spoil has been acquired by each contrivance. As a matter of course each individual inventor would sing the praises of his own particular progeny; and with perfect good faith, too, for had he not thought it the best he would naturally have adopted some other one. It is, however, not a little amusing to observe how enthusiasm will sometimes run away with a photographer who rides his hobby very hard. We remember not very long ago reading a letter published in the pages of a contemporary, in which the writer recommended the use of a bag for changing his plates, into which he also put his head while performing the operation, and wound up his communication by stating, "that he was sure any one who tried it would be certain to like it."

Now, joking apart, we have no doubt that the writer of the above-named letter really did enjoy the operation—not *per se*, of course, but for the results he obtained thereby; and there is something very genuine in the earnestness displayed in the pursuit, and the eagerness shown to communicate a portion of his pleasure to others.

Again, the numerous variations of the dry processes will probably this year stand a fair chance of being accurately compared one with another under almost every conceivable variety of circumstances. It is to be borne in mind, however, that every photographer, even if he be an able manipulator, is not necessarily qualified to observe comparatively, excepting so far as he himself is concerned; therefore, in all the reports that may hereafter be published, it will be well to note very particularly the personal habits of the operator so far as they bear upon the subject. The fact is, that very many of the conflicting statements that appear are due, not so much to the real merits of the respective processes, as to the idiosyncrasy of the operator.

We notice in a French journal devoted to photography, *La Revue Photographique*, two letters, signed respectively "H. Collard" and "A Subscriber," complaining of want of success in attempting to repeat the experiment of development in ordinary light, as indicated by Mr. Young, of Manchester. One of the two correspondents denominates it Mr. Young's process, and inquires in what consists the benefit, seeing that the number of operations is not lessened?

The letters of these gentlemen both explain the cause of the respective writers' failures, inasmuch as each one employed a simple film of collodion, instead of one *albumenised*, as was expressly intimated as necessary to success by Mr. Young, who

also mentioned the fact that collodion alone did not appear to possess the same property. It is doubtless owing to the fact of their want of access to the original document that the experimentalists committed the mistake.

In reply to the question asked, we would first of all remark that Mr. Young did not put it forth as a new *process*, but simply communicated the fact as a singular phenomenon that he had observed, and which he considered (very correctly) as one worthy of being recorded, being assured that no scientific *fact* can by any possibility be regarded as insignificant, as the time will surely arrive when each will be utilitised. With regard to that one under consideration, there are photographers who can employ it with advantage even now, as, for instance, in developing a dry plate when away from home, when it would be extremely difficult to *improvise* a dark room; for it must be borne in mind that in order to develop a negative properly it requires inspection during the operation, while to merely dissolve out the iodide of silver, commonly called fixing, the affair can be managed just as well without seeing it as when under observation the whole time.

Personally we can give testimony as well to the utility as to the existence of the phenomenon.

We learn from *The Photographer* — a MS. journal into which we are allowed to peep, and from which we are privileged to cull such scraps of information as we may judge likely to be of interest or amusing to our readers—that an "official report" from a Committee appointed by a northern Photographic Society for testing the merits of various landscape lenses is to be looked for in the number of the *Journal of the Photographic Society* that appears simultaneously with this.

Now, in the absence of the "official report,"—which, of course, we have not yet seen — and relying solely on the "gossipping" account of proceedings given by Mr. Taylor, we cannot refrain from expressing our surprise at the very desultory nature of examination made.

That the lenses constructed from the recent Petzval formula should give marginal lines curved outwards at the extremities, and those of the ordinary landscape form marginal lines curved inwards at the same parts, might have been *deduced* from a knowledge of the position of the diaphragms in the respective lenses; but in a formal examination it is of course proper that these facts should have been verified.

It is asserted that the meniscus lenses embraced a greater angle of view than the Petzval form; but pending a detailed description of the method of ascertaining this point, we may express our conviction that the statement wants modification to be absolutely correct — thus, "that the former embraced a greater angle of view, *in a given space*, on the plane of delineation."

As the comparison of a number of lenses is a task of no trifling labour, if properly performed, and while there is much able "testing power" running to waste for want of a little judicious guidance, it may not be amiss if we indicate succinctly what are the particular points to which the attention should be consecutively directed. We may premise that optical examination, without taking proofs, we regard as *useless*, except comparatively for lenses all constructed by one formula.

1. *Coincidence or variation of the chemical and visual foci, and if the latter, the approximate amount.*— This is best arrived at by aid of M. Claudet's admirably-designed instrument — the Focimeter — but in its absence a printed paper placed obliquely to the axis of the lens is to some extent available.

2. *Correction for spherical aberration.*—This can be ascertained by using alternately only *half the area* of the lens under trial, first the central, then the marginal parts being employed to delineate the object examined. A piece of brown paper or cardboard, cut in the forms of a ring and a disk, is always available for the purpose.

3. *Flatness of field,* — or rather the amount of its sphericity.

4. *Amount and direction of marginal distortion,* — the amount only requiring actual trial, since the direction can be seen at once by mere inspection of the lens.

5. *Angle of picture,* — how much capable of being included without too excessive an amount of distortion of the image, or indistinctness from sphericity of field.

6. *Definition.*—This will depend materially upon the spherical correction when a large aperture is in use, and it is only with a large aperture that it is needful to examine.

7. *Quickness in working.* — This will depend partly upon the defining power, as governed by the correction for spherical aberration, because the available *angular* aperture of the lens is mainly influenced thereby, partly upon the number and perfection of the surfaces through which the rays have to be refracted, and partly upon the quality of the glass of which the lens is formed. The mere *size* of the diaphragm employed is not important, except as affecting the *angular aperture*, so that by attending to this last-named point it is quite possible to compare accurately the relative quickness of lenses of very different focus, provided that the object delineated be sufficiently remote.

It will be observed from the preceding that there are at least *seven* operations which each lens examined should undergo; but in fact some of these include the performance of more than one experiment. However it must be conceded that by judicious management, several of the requisite questions can be sometimes answered in part or wholly at one operation.

Of the proper centering of the component parts of the various lenses it is almost needless to inquire, as it is to be presumed that no optician would neglect the necessary precautions; but some notice of the peculiarities of the various mountings might well and advantageously be incorporated in any formal report on the qualities of photographic lenses. There are generally far too much brass and too many screws, and the latter are very apt to be made with too fine a thread and too many turns. Diaphragms also are frequently adapted in a very clumsy manner, and "caps" are too often made as if with the special view of easily getting out of order. Although the mounting of a lens has comparatively little to do with its optical qualities, it must be admitted that it has much to do with the comfort and convenience attendant upon its use, and the more the operator's mind is disembarrassed of troublesome manipulatory details, the more he will be likely to address his whole attention to the production of works bearing the genuine stamp of art.

We shall be curious to see how much or how little of the above has been investigated under the auspices of the "chiels o' the north."

NOTICES OF RECENTLY PUBLISHED STEREOGRAPHS.

When a professional photographer of considerable reputation for his skilful and artistic stereographic productions, whose success is partly dependent upon some peculiarity in his mode of operating, is so liberal as to communicate his method of procedure, whether with or without solicitation, for the benefit of the public, we have no hesitation in asserting that the photographic portion of it at least will duly appreciate the boon, and unanimously accord its best thanks to the gentleman who acts in so generous a spirit. Such an one as we have been describing is Mr. Russell Sedgfield, who was kind enough to communicate the method by which he has produced some of the most successful stereographic interiors of our Cathedrals that have been yet offered to the public.

The communication to which we have made allusion, appeared in our number of Aug. 15, at page 197, and we strongly commend it to the consideration of those engaged in similar work to that for which the proceeding was designed, not only because "there are glimmerings of common sense in the recommendation" (as a facetious friend of ours sometimes approvingly remarks), but because also the results tell in its favour. A considerable number of specimens accompanied the communication, and we propose to remark upon them, firstly as illustrative specimens, and secondly as photographic productions.

There are few persons who, being usually in the habit of taking out-of-door subjects, have attempted the delineation of interiors, without experiencing at first many very mortifying disappointments, and this is chiefly owing to the extreme difficulty of realising the extent of degradation of actinic activity in such localities, the deep shadows especially being almost impenetrable. It is generally judged that two or three times as long an exposure as is requisite out of doors will be sufficient, but this is far from being the fact; and then, as Mr. Sedgfield truly observes, an additional obstacle is introduced in the concentration of the free nitrate of silver from evaporation, and the consequent production of stains; to which we may add, a reduction of sensitiveness, from the additional strength of the nitrate of silver enabling it to dissolve away a portion of the iodide from the film.

Now with regard to the specimens sent (sixteen of them), they are, with one single exception, free from stains or flaws of any kind; the one excepted *not* being an interior, and that only slightly affected with minute pin-holes in the sky, a defect in all probability quite extraneous to the particular process employed. Many of the shadows, which must from their nature be very intense, are all transparent, and exhibit correctly every particle of detail that the eye can see; there are no chalky high lights, while the gradation from deep shadows to high lights throughout the whole gamut of semitones is harmonious in the extreme. What more can we say for the fruits of the process?

But this is not enough for the works themselves, which we have carefully and delightedly surveyed. It is quite delightful, after seeing in many of the shop windows where sterescopic slides are sold, such a collection of trash as is frequently exhibited, to enjoy the contemplation of some of our finest architectural subjects so admirably portrayed as in the series before us.

We have recently been treated to a mental visit with Mr. Woodward to one of the lovely dales of Derbyshire; we are now being refreshed, in like company with Mr. Sedgfield, with the cool shade and delicious calmness of the "echoing cloisters and long-drawn aisles" of Norwich and Ely Cathedrals, and some of the churches of Norfolk. We inspect them all at our leisure too, lingering over the cunningly-sculptured stone and wood-work, without the impatient gesture of the attendant verger to recal us with a sudden shock to the unpoetical present.

Of the whole series before us, there is perhaps not any one amongst the interiors more beautiful than The Altar Screen in Ely Cathedral, which must be in reality a perfect gem of carved work. Every inflection of the rich tracery is most faithfully rendered; the subject of the sculpture itself, various passages in the life of Our Saviour, being distinctly visible, and yet the greater part of the screen is in shadow, with the exception of a few of the ornamental figures on the top. The tessellated marble floor in the foreground, the stained glass window behind, and the chequered light falling through one of the side windows, combine to produce a most exquisite effect.

The Choir of the same Cathedral, though equally well executed, is not quite so interesting as the preceding; it is nevertheless extremely beautiful, and includes a magnificently-sculptured monument in the right-hand corner.

The Nave, with the Choir in the distance, forms a third one of these charming interiors, we have also an external view of the East End, and a general view from the Park; but these do not complete the series, illustrative of Ely Minster, as we understand that there are several others taken by this artist. We may remark that the external views are in no way inferior to the internal ones in point of execution.

The Interior of St. Stephen's Church at Norwich is a capital illustration of the value of the process by which it was taken. The dark wood-work of the roof and sittings, contrasted with the whiteness of the stone forming the structure itself, the proximity of some of the ornamental ends to the seats, and the remoteness of others, must have been very trying to the capabilities of the film, as well as to the manipulative skill of the operator.

Norwich Cathedral, though not nearly so rich in ornament as its brother of Ely, being in fact comparatively plain, yet furnishes three interesting interior subjects, viz.—The North Aisle, The Choir, and Chantrey's Monument to Bishop Bathurst. An external view of the West End, and a distant one from the Meadows near Sandling's Ferry form part of series.

The remains of Castle Acre Priory form a subject alike interesting to the antiquary, the architect, and the lover of the picturesque. The point of view is admirably chosen, and the execution every thing that can be desired.

The Ancient Entrance to Norwich Castle will suit our archæological friends, as also The Abbey Gate at Bury St. Edmunds.

The Ancient Bridge, from the Abbey Grounds, in the same locality, in addition to its antiquarian interest, possesses also the charm of being calmly picturesque; in fact its antiquarian is completely outbalanced by its artistic value. The clear waters of the stream, which appear as transparent as unsullied crystal, reflect a portion of some building behind the bridge, which building is itself not visible to the spectator, the reflection being broken up by the reeds and other aquatic plants in the stream.

Two low arches of a quaint and massive bridge, overgrown with ivy, are visible, and behind the bridge, at some distance, the outstretched branches of a stately elm tree are seen; while a figure—unless we are mistaken, that of the artist himself—stands on the bank in quiet contemplation of the water. It is altogether a very beautiful composition.

With the notice of one more subject we shall bring our remarks to a close. An external view of St. Peter's Mangroft Church, Norwich, is interesting in an architectural point of view, and highly effective as a stereoscopic subject, being seen through a vista amongst houses and other buildings, and with numerous figures, and what artists call "stuff" happily disposed in the foreground.

THE SOLAR CAMERA.

It is never without considerable reluctance that we feel called upon to make remarks that appear to express disapprobation or detraction; it was, therefore, with no little regret that we felt bound to append the few words of dissent from the statements made in our two last numbers by Mr. Atkinson and Mr. Woodward, relative to the solar camera. But lest the objections made might be taken in a more extended sense than we intended them to bear, we deem it requisite to enter more fully into the subject without further delay. We may state at once then that we have no doubt, in fact we never have had any doubt, that the solar camera would produce good and enlarged proofs from small negatives, with all characteristic fidelity, and with a certain amount of sharpness, dependent in a great measure on the excellence of the portrait combination employed as the delineating agent. Our doubt was confined exclusively to there being any novelty of principle involved, and consequently to the justice of the claim set up for *exclusive patent rights*. We assert that our doubt was confined to this point before we had seen the apparatus, but since we have done so it exists no longer. In making this statement we must beg our readers to bear in mind that it is but the opinion of an *individual*, and that one *not* "learned in the law." We now proceed to lay before our readers the grounds upon which the opinion we have expressed was founded.

At a meeting of the Photographic Society early in the year 1853, we were shown (privately) by Mr. Wenham, three or four *life size* portraits upon paper—two of himself, one of his brother, and one of a lady—and these were in every way at least equal, we think better, in quality as regards resemblance, definition, &c., to that we saw the other day at the studio of Mr. Kilburn, in Regent-street. It of course could be no mystery to any one acquainted with optical science regarding their method of production so far as principle went; and after discussing some of the details with Mr. Wenham, we instituted a series of experiments with a view to ascertain how far it would be possible, with the means then at hand, to produce enlarged negatives by a double operation, fit for printing from. This we determined was not worth pursuing, owing to the reduction in the brilliancy of definition, which suffered somewhat in every operation, whilst defects introduced at any stage were faithfully repeated in the next.

Although we abandoned the practice of producing enlarged negatives for the reason given, we found that a very pleasing effect could be produced by printing enlarged positive impressions by transmitted light upon glass plates, and then backing them up by an opaque white varnish.

At the request of the Secretary of the Photographic Society papers were read by both of us at the meeting held on 1st December, 1853, a report of which papers is to be found in Vol. I of the *Journal of the Photographic Society*, p. 142 to 146.

On reference to Mr. Wenham's paper, it will be seen that he made use of a magic lantern, employing a transparent stereoscopic picture as a slide and substituting a portrait combination, reversed in position as an object glass—when, he says, "the definition became perfect, so much so, that I at once saw that if the picture

were illuminated by transmitted sunlight, the impression could be readily fixed on sensitive paper with all its minuteness of detail." Subsequently it is explained how a common swing looking-glass was employed as a reflector, to throw the sun's rays through the apparatus.

It will no doubt be objected that eventually Mr. Wenham dispensed with the condensing lens of the arrangement, and printed his proofs by development. He did so for the very good reason that he could produce "sharper" results thereby, as stated in his paper, and without the protracted exposure otherwise necessary. But this does not affect the fact of his having originally adopted the same arrangement as that now in use in the solar camera. But we have very distinct evidence that the *principle* was in use *as applied to the production of photographs* long prior to the time mentioned. We are credibly informed that the Hon. Henry Fox Talbot actually made use of the same principle in the very earliest days of photographing on glass; and we know for a fact, that the Rev. J. B. Reade produced photographs *upon white leather* by *aid of the solar microscope* at about the time of the first introduction of the calotype process, the proofs of which we have personally inspected, and the actual rate of production we could, if needful, readily ascertain from that gentleman. In this case every thing included in the solar camera was employed; for singularly enough the said camera is merely comprised of the box, condensing lens, and reflector — the portrait combination which takes the place of the ordinary microscope lenses not forming a part of the arrangement claimed by Mr. Woodward; in fact its employment in this way was too notorious to permit of its being included.

We have already admitted that the proofs printed from good negatives by means of the solar camera are faithful transcripts of the originals, so far as resemblance is concerned, but very inferior in definition — so much so that few persons would be quite content with them if unaided by the touches of an artist, while certainly no photographer would regard them as works leaving but little to be desired.

We believe that there are few, if any, who employ the instrument that would be inclined to dispute this assertion — certainly not Mr. Kilburn, to whose courtesy we are indebted for an opportunity of examining the instrument and seeing it in action, and who, by the way, expressed himself well pleased with the apparatus.

That it should be deficient somewhat in definition is a necessity of its construction — partly because the method of illumination adopted introduces some disturbing agents, *e.g.*, dispersion of the solar rays by refraction through the condenser; change of their direction in consequence of the sun's or rather the earth's motion, &c.; for although the reflector is made to incline at any angle, and to revolve about the axis of the condenser by means of a not very convenient piece of rackwork, it is not arranged as a *heliostat* as might have been readily done at no more expense than what is already incurred; and partly because the optical arrangement is not that one best adapted to produce an undisturbed impression upon a plane surface from one of a like form.

It was to obviate the errors above named that Mr. Wenham employed parallel rays of direct sunlight and dispensed with the condenser. This also involved the use of printing by development, unless the operator happened to be possessed of an unusual stock of patience; but at the same time it permitted the use of a diaphragm, thus diminishing errors arising from spherical aberration.

We may remark, *en passant*, that though Mr. Woodward does not use any diaphragm actually, yet in effect an equivalent is introduced in consequence of the convergence of the rays from the condenser at a spot very near to that where the diaphragm should be placed, consequently his impressions also are nearly free from disturbance, arising from the sphericity of surface of the lenses.

We have now stated our reasons for the assertion previously made — our readers can judge for themselves whether or not they are well founded; and we declare emphatically that, as regards sharpness of definition, Mr. Woodward's specimens are inferior to those we saw of Mr. Wenham's.

Before finally quitting the subject we may as well indicate how the chief objections which we have taken to the construction of the solar camera may be obviated.

If it be desired to print upon ordinary chloride paper without development, we believe that convergence of the illuminating rays is a *sine qua non*; we must therefore be content to put up with the slight weakness of definition arising from this cause. We need not, however, introduce the disturbance from dispersion, which we take to be far more obnoxious, nor need we incur the additional loss of light from absorption and reflection at the surfaces of the condensing lens, with which we can readily dispense; and, lastly, by employing, instead of the portrait lens, one of the form recently introduced by Professor Petzval, and generally known by the designations, "orthographic," "orthoscopic," "caloscopic," &c., we avoid almost entirely the inconvenience otherwise arising from sphericity of field.

It will be remembered that when our objections to that form of lens were strongest we fully recognised its value for *copying* purposes.

The reflector, instead of being a plane silvered glass should be *concave*, and so disposed that the rays reflected from its surface should converge to a focus precisely at the spot occupied by the diaphragms of the orthographic lens, which, like the portrait combination, should for enlarging be reversed in position. The distance between the mirror and lens should be fixed, though the former may be allowed to turn freely in any direction by suitable contrivances well known. The best form of curvature for the mirror would be a portion of a paraboloid of revolution, as from a surface of this form parallel rays are converged to an absolute point; but we believe that a portion of an elongated ellipse would answer well in practice, and that even a spherical surface would be far better than a plane mirror and lens.

The distance between the reflector and the enlarging lens must in some measure depend upon the focal length of the latter; but in general terms it should not be less than double the length of its principal focus, thus allowing sufficient space for adjusting the negative so as to allow for any required degree of enlargement.

In conclusion, we have little doubt that, if the arrangement above indicated were adopted, employing the parabolic reflector, placed at an average angle of 45 degrees so as to reflect horizontally the light from the zenith, that direct sunlight might be dispensed with for printing upon ordinary plain or albumenised chloride paper, and without much longer exposure than that requisite in an ordinary printing frame. As the varying position of the sun would not in this case interfere with the zenith, no great inconvenience would arise from the protracted time of exposure, whilst the definition would, unless we are greatly mistaken, be infinitely superior to anything that has yet been seen of this kind. The larger the size of the mirror, provided it be placed at a proportionate distance from the lens (of course having a corresponding focal length), the more rapid would be the action of the apparatus, but the more costly in construction. We would, however, draw attention to the fact that it would be useless to include an angle of converging reflected rays greater than the *angular* aperture of the enlarging lens, as the surplus would be simply wasted — not used.

ORGANIC SALTS OF SILVER IN THE DRY PROCESSES.

WHILE spending the day recently with our old friend, Mr. Rosling, whose name is well-known as that of a skilful photographic amateur, in chatting over the subject of collodio-albumenised plates, we expressed some surprise at the lengthened exposure which our friend found it necessary to allow for the plates he was then using, and which were prepared by the original method devised by M. Taupenot, a process that Mr. Rosling esteems above all other dry processes.

The conversion of all the free nitrate of silver into an insoluble haloid or organic salt of the same metal, by washing the excited plate in a solution of chloride of ammonium, sodium, or other analagous compound, or by a similar proceeding with citrate, oxalate, or phosphate of soda, having been lately recommended by Mr. Keene, Mr. Burnett, Mr. Hill, Mr. Hannaford, and others, as rendering the double films *more sensitive* to the action of light, we advised our friend to try the effect upon his Taupenot plates; for, although on trial with Fothergill plates, we were by no means satisfied that any marked increase of sensibility was attained thereby, we think it highly probable that it may prove to be the case *under a judicious mode of development*.

Mr. Rosling has since favoured us with the following note relative to the result in his hands: —

"DEAR SIR, — I have tried a bath of citrate of soda for the Taupenot's plates after the last sensitising, and *cannot* find that it increases the sensitiveness in the least — if anything, I fancy it rather diminishes it. I still think there is a little advantage, as it produces a somewhat blacker tone, which is preferable for printing. I tried it on two stereoscopic plates, in two separate cameras, with a pair of lenses which work together in one camera, and produce the pair of pictures exactly alike. I gave the first picture in each

camera two minutes, and the last four minutes, working both cameras together, so that I am fully satisfied on this point. I intend to try the keeping qualities of each.

"I remain, very sincerely,

Reigate. "ALFRED ROSLING."

The comparison was made between a collodio-albumen plate, washed with plain water, and another with solution of citrate of soda, each plate being placed in a bilens stereoscopic camera, each plate having one-half exposed for two minutes simultaneously with its fellow plate, and the other half in like manner for four minutes. We are of opinion that by slow development, as recommended and employed by Mr. Kibble, the advantage might show itself, as the citrated plate would probably bear longer development than its fellow, without staining. The experiment was well designed and fairly performed, and is decidedly of value.

PHOTOGRAPHS OF MICROSCOPICAL OBJECTS.

THERE is, perhaps, no branch of photography in which a wider field is open to a skilful and enterprising manipulator than that of producing a well-arranged series of true microscopical studies; not only on account of the beauty and interest of the subjects to be depicted, but because, so far as the public are concerned, it is almost untrodden ground. It is true that here and there a few well-executed specimens have made their appearance now and then at our exhibitions, but, as a rule, they have been simply distinguished as "Studies of Microscopic Objects;" and nine times in ten the passing remarks of casual observers amount to the words, "What queer-looking things!" while the names of the objects delineated, when appended, generally get classed as "crackjaw." It is true that occasionally a microscopist will readily enough recognise some of his old friends; but, alas! we own it with sorrow, the best of the photographic depictions present but the mere caricatures of the brilliant originals. They may be, and sometimes are, very valuable for certain purposes, but few of them are such as to be cared for, much less coveted as works of art; whilst we have but rarely indeed seen the novice take his first glance at the objects themselves, without, at the same time, witnessing an unmistakeable degree of enthusiasm, accompanied by expressions of wonder and admiration.

Now why should photography be thus behindhand in depicting some of the most beautiful and interesting subjects to be found in the whole creation? The question is not difficult to answer. It but rarely happens that the accomplished microscopist and skilful photographer are combined in the same person; and when they in rare instances are so, it is certain to be amongst amateurs, who generally have other pursuits as a business or occupation, and are thus deficient in very important elements to the production of an extended and systematic series of illustrations, viz.—time, and opportunity to use it.

Nor must it be forgotten that even if both qualifications requisite are brought to bear upon the pursuit that the circumstances under which they have to be exercised are entirely new, and the optical difficulties, sufficiently great in themselves, are aggravated by the fact that the lenses are not constructed with a view to their diactinic qualities.

These remarks have been called forth in consequence of our having been favoured with some specimens of photo-micrography, the work of Mr. Archibald Briggs, of Liverpool.

They are evidently the production of one enamoured of his occupation, but we must candidly admit that they are sufficiently good to make us wish them better—that is, they strongly recal to mind the images they represent, but the glory has been shorn, the delicate membrane, the gem-like brilliancy, are absent from their respective places. This is not so much the fault of the operator as that of his tools, and the want of knowledge upon certain points connected with the pursuit under which all are as yet suffering. The day will no doubt come when both of these drawbacks will be removed; but, for the present, we must be content with such presentments as our limited means will enable us to effect; and certainly those before us are of more value to the public than any we have hitherto seen, for not only are they well executed, so far as the means allow, but they are accompanied by a short description appended to each proof, together with an indication of the degree of enlargement under which the several objects have been taken.

The specimens are four in number, and consist of

1st. The epidermis of the common white caterpillar, enlarged about eight diameters. The negative from which this is printed was produced, not with the microscope, but by aid of a photographic portrait combination attached to the solar camera, and was taken *instantaneously* upon one of Dr. Hill Norris's dry plates.

The details of those parts *not* of a yellow colour are extremely well brought out; but where this colour prevailed, they are, as might be anticipated, deficient—as, for instance, in the beautiful fringe-like set of hooks with which the supplementary feet are furnished.

2nd. Frustules of the Isthmia Nervosa, the siliceous cuticle of a very interesting class of plants known to botanists under the name of *diatomacæ*, or brittleworts, as Lindley has designated them.

This plate is far less satisfactory than the preceding; at the same time, it is a much more difficult subject to handle. The frustules have a considerable degree of thickness, and are anything but flat, while the structure and constitution (the latter resembling the purest crystal) are but ill capable of representation in mere black and white.

3rd. Section of the spine of an Echinus, one of those prickly-looking balls found on our sea-shores, and variously known as sea-eggs, sea-urchins, &c. The specimen operated upon has not been happily selected, being one of the least complex and beautiful of these exquisitely-constructed objects, some of which present the most charming resemblance to elaborate Gothic tracery. Neither has the specimen been too well cut, and appears to have been rather too thick. It will, however, serve to open the eyes of the novice to the singular and admirable contrivance for insuring strength combined with lightness.

4th. The tracheal vessels of the silkworm. This is perhaps the most effective object of the series as a photograph, the spiral coils of fibre designed for keeping distended the elastic membrane constituting the tube, being beautifully rendered. But here again the membrane itself is lost, and no wonder, for it is only by careful manipulation and peculiar illumination that it is apparent to the eye in the microscope, when drowned as it were in a flood of light.

We are glad indeed to see this first instalment of what may entice many to the study of microscopical science, a study that we have followed more or less for a quarter of a century, and which we are daily more and more convinced is absolutely inexhaustible.

It is, however, by following out the delineation of a special class of objects that we think most good is to be done; and if any photographer has a mind to commence such a work systematically, we will suggest one that we believe would be interesting, *popular*, and not too difficult to begin with—say, for instance, a series of sections transverse, tangental, and radial, of all the kinds of wood in ordinary use for cabinet, building, and shipbuilding purposes. We have not a doubt that such a series, if well executed, would meet with a ready and extensive sale.

OXYPHENIC ACID, A SUBSTITUTE FOR PYROGALLIC ACID.

MR. WAGNER was the first to suggest the substitution in photography of oxyphenic acid C^{12} H^{6} O^{4} for pyrogallic acid, which is very costly. It can be prepared in the following manner:—Take a given quantity of crude pyroligneous acid, and distill it, as is done when pure wood spirit is obtained: agitate the syrupy mass, the residue of distillation, in contact with a concentrated solution of common salt. The salt dissolves only a very small quantity of the bituminous matters, but removes all the oxyphenic acid contained in the crude pyroligneous acid. It is filtered to remove all the bituminous matter, and the filtered liquid is agitated anew with an equal quantity of ether. The ether dissolves the oxyphenic acid, and retains with it a certain quantity of acetic acid and oil of tar. The ethereal solution is decanted and submitted to distillation. When nearly all the ether is volatilised, the temperature is raised, and a current of carbonic acid passed at the same time into the retort through the liquid. The current of gas drives off the acetic acid, then the oxyphenic acid and a brown oil; the middle portion is received separately. It is then cooled, and a crystalline magma is obtained, which is pressed, then distilled anew, or sublimed in a current of carbonic acid, forming colourless crystals of pure oxyphenic acid. They form rectangular prisms, perfectly dry at 176° F., which melt at 230° to 240°, the liquid resulting from their fusion boils at 464° to 473°, and is reduced into a colourless vapour, which becomes liquid on cooling, forming magnificent crystals. These crystals are very soluble in water and alcohol, less soluble in ether; the aqueous solution exhibits a slightly acid reaction, and a faint odour of butter: it reduces very readily the salts of silver, and the chlorides of gold and platinum. Rendered slightly alkaline by the addition of a little potash or caustic ammonia, it rapidly absorbs oxygen, becoming first green, then red, which distinguishes it from pyrogallic acid, which is first brown, then black.

IODIDE OF CALCIUM.

The mineral best adapted for preparing iodide of calcium is gypsum, or natural sulphate of lime.

Take eight parts of calcined gypsum and mix it intimately with three parts of carbon. Place it in an earthen crucible, and submit it to a light red heat for about an hour.

The sulphide thus obtained is mixed with water, and iodine projected upon it little by little, frequently stirring the mixture, the temperature of which rises considerably during the operation. Continue adding iodine until the liquid is no longer colourless after the addition, then add a little slaked lime, and leave the liquid to repose for a few hours.

The foreign oxides, arising from the gypsum or carbon—alumina, silica, iron, and manganese — remain as precipitates. The liquid which is nearly colourless and slightly alkaline, must be quickly evaporated to dryness.

The heat must be stopped as soon as iodine begins to be disengaged. The crust of iodide is detached and put into a porcelain crucible, closed by a cover. This crucible is placed in an earthen crucible, the intervening space between the crucibles being filled with powdered charcoal, and a cover fitted to it. It is then heated for half an hour at least.

When removed from the fire and allowed to cool, break the porcelain crucible, and detach the iodide, which appears under the form of large scales of a pearly lustre, like chloride of magnesium, and which, like that salt, is easily crushed under the pestle; very different in that respect from chloride of calcium, and the iodides of barium and strontium, which are much more resistant, without micaceous structure, and indecomposable by sodium.

A New Use for Photography.—A correspondent of the *Liverpool Mercury*, Mr. F. D. Murray, says:—"Excuse my troubling you on a subject of more importance as regards public taste than public interest. It is the insertion in tombstones, monuments, &c., of the photograph of those who are taking their last sleep beneath, leaving to parties themselves or their friends the choice of that period of life at which such "photograph of remembrance" should be taken. I think it would be a pleasing and loving memorial for friends, relatives, and acquaintances to look upon. The only way in which my proposition affects public interest is, that photographs so placed would invite the visits of thousands, and those thousands would reap the benefit of the influence exercised by a stroll through a graveyard, and which influence would, in my opinion, tend to make us better men and wiser women."

Meetings of Societies.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

This Journal being the official organ of the above-named Society, it becomes our duty to remind the members thereof that the first ordinary meeting for the ensuing session will be held as usual at Myddleton Hall, Islington, on Wednesday evening, 28th inst. The chair will be taken at eight o'clock.

It is requested by the committee that papers and other communications for the Association be forwarded to John Barnett, Esq., Honorary Secretary, 9, St. Peter's Terrace, Islington, to whom also candidates for admission as members should apply.

Apparatus, &c., intended for exhibition at the meetings should be forwarded to Myddleton Hall, to the care of the Honorary Secretary, by *seven* o'clock on the days appointed for the meetings.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

The first meeting of this Society for the present session was held on the evening of Tuesday, the 30th ult., at the Odd Fellows' Hall. Mr. T. Morris presided.

Woodward's Solar Camera was the subject appointed for discussion. In the first place, Mr. Hart, a member of the society, narrated the experiments he had made with a very rude and imperfect apparatus, and with the additional disadvantage of having had very little previous practice in working the paper process. Still he laid before the meeting several tolerably good enlarged portraits. One practical hint which he had gained from his short experience was, that the size of the negatives should be regulated by the size of the picture. Another was, that in the focus of the double combination, lenses of different makes produced different results as regarded the sharpness of the picture. He was not prepared to say which process would be the best, but he was inclined to think that a good, clean, and easy method of developing would secure the best results. There could be no doubt that splendid work would ere long be done by Mr. Woodward's instrument, and he hoped that no attempt would be made to deprive him of the credit which was justly his due.

The Chairman: I have had some experience as to the instruments, but not much as to printing pictures, though I have had the opportunity of seeing what others have been doing, and have been present at many experiments to get these pictures perfect within a reasonable time. The delay incidental to the process has been one of the objections. Some operators have taken as much as three or four hours, and others as much as two days: some tell me they have exposed pictures for four hours, a good size, and that it would have been a nice picture if they had only given it another hour. Of course it is possible to make a sensitive paper so insensitive that it cannot develop; but the portrait I now produce (a remarkably vigorous one, nearly life size) was printed to-day in two minutes, and, if anything, seems somewhat overdone. It is a developed print but by a new process; and altogether not more than half an hour was occupied, though I am convinced those pictures can be taken in two seconds. As to Mr. Hart's remarks with reference to different lenses, one point must be borne in mind in selecting a lens for a solar camera. The condensing lens is of a given focal length—17 inches in large instruments—and whatever combination you employ to produce your picture, you should so arrange it that the pencil of light crosses exactly in the centre of the front lens. It is essential that before you attempt to focus your picture, the lens being a fixture and the combination inserted, you should so move the rack as to bring this lens either outwards or inwards until you get this pencil of light exactly upon the centre lens. Then it does not matter how distorted your picture may appear upon the screen, as you may move it by the negative being moved backwards and forwards.

Mr. Osborn: Would that have any effect upon the time of printing?

The Chairman: Decidedly, and also on the sharpness of the picture. We all know that if you take a lens that produces a sharp clean picture, of a given focal length, you will always find that that lens works quicker than one which gives a soft picture. The picture I now produce was taken with a quarter-plate lens. The process by which it was taken is by no means the most sensitive. They can be taken by artificial light with this instrument. The developing process is an American one.

Some remark having been made as to developing trays, Mr. Turner (a co-worker with Mr. Morris in the experiments) said it would be found necessary to have them of glass, and there should be one for the silver and another for the albumen. Operators must also be particular what kind of paper they had for the development; it must be very good. The paper ought not to be touched at all with the finger, or the picture would be spoiled. He (Mr. Turner) had no doubt that ultimately they would get a picture in twenty or thirty minutes by means of the ordinary gas-light. Walking across the room while the development was going on must be avoided, as vibration would spoil it.

The Chairman, in answer to a question, said he had no doubt that development would be found the most economical process, especially for large prints.

A vote of thanks to Mr. Hart closed the proceedings.

NOTES OF A PHOTOGRAPHIC TOUR IN THE HOLY LAND.

No. V.

The Convent of Saint Saba is one of the most singular places in the world. Its origin is easily explained. In early Christian days, when monachism began to prevail, and when the idea gained ground in the Church that sanctity was to be attained by a hermit's life, the Wilderness of Engeddi offered special inducements to the devotee. It was, as it now is, a wild, bleak country; mountains broken up by deep ravines, destitute of food for man, almost destitue of food for wild beasts. In the sides of the deep ravine of the Kedron were numerous small grottoes and caverns, in which many hermits took shelter. Here was the cell of Saint Saba, a good and great man, who performed miracles. Other cells were near. Little platforms of rock were hewn out to connect one with the other. The hermits formed a community, and at length began to build stone huts on the shelves of the rock. Then wealthy men visited them, and began to build them chapels and rooms, clinging to the rocky hill-side. So grew this marvellous building in mid-air, now looking as if it were growing up to heaven, and now as if it were falling down to the depths. It now belongs to the Greek Church, and is inhabited by Greek monks.

I presented a letter under a high window in the wall, and the basket was lowered to receive it. A few moments later the small door in the wall was opened, and I passed in.

The interior of the Convent is not worth describing. There is the tomb of the saint, a cave full of hermit's bones, a fine alterpiece by Murillo in the chapel, some curious old books in the library, and the usual cells of the monks.

I accepted their hospitality for the night, much as I abhor a Greek convent. The fleas in them are armed with the spears of the men of Marathon. Thrice I composed myself to sleep that night, and three times I sprang from my couch to the middle of the floor, as a new troop of the blood-thirsty villains made an attack upon me.

Think of me alone in that large guest-chamber, the moon shining down the ravine and into the windows, pacing up and down the room, shouting out an occasional stave of a song to keep up my spirits, and to keep down the ghosts of Saba and his followers. My profane songs must have disturbed the vigils of the holy brethren; for two or three times I heard a sandalled foot-fall on the pavement outside, and saw a face too solemn and pale, even for a ghost's face, at the window which opened on the little court next to the tomb of Saba. I fear the monks repented them of their hospitality.

Once, I believe, I fell asleep; for as I lay on the cushions, with my boots on, and my *tarbouche* drawn down over my forehead, with a determination that I should bid defiance to fleas and all other midnight marauders, there came stealing over my brain and heart a silence and a calm, delicious and holy, which I have not words to describe. And then a dream took possession of my soul. I was a boy, in the dear land of home: the breath of a summer Sunday morning was on my forehead. I walked down that shady lane where the elm-trees meet overhead, and the glory of the day scarcely prevails to reach the ground through the green leaves. And then over the hills came, clear and musical, the bell from the old church on the green; and I walked on till I came to the church door, and the great bell pealed overhead as I went up among the graves; and so I passed on into the church, and ——

How swift are the wings of our dreams. I could have slept but an instant, and the convent-bell was ringing for midnight mass, and I was awake again. But I had dreamed gloriously! I would go down to Saint Saba again to-night, spite of Bedouins and fleas, could I hope for such a dream once more. I am a far wanderer, and it is long since my weary feet walked that old country road.

I went into the dim chapel and prayed with the monks. The scene was picturesque: it reminded me of one of Daguerre's wonderful dioramic pictures, *The Midnight Mass;* but I was sleepy. Morning found me in the same condition.

Pardon me for breaking off abruptly. There is a terrible row outside among my Arabs, and I must go and see what is the matter!

I was interrupted by an uproar outside my tent. I had some misgivings as to the cause of it, as John had got into trouble some days previously with the Pasha's soldiers, and I expected nothing less than that the hour of our annihilation had arrived. I seized a pair of revolvers and rushed forth. I found that the row among my Arabs was caused by the approach of a distinguished visitor, no less a person than Mohammed Bey, a wealthy and intelligent Turkish gentleman, resident in Damascus. He had heard at Jerusalem that a necromantic infidel was pursuing his black art in the neighbourhood, so he came to see and judge for himself. A great favourite everywhere among the Bedouins, his approach elicited shouts which were very unusual among my quiet guard. I hastened to meet the Bey. About a hundred yards from my tent stands the Pillar of Absalom, that melancholy memorial of a disobedient son, at which Jews, Turks, and Infidels, cast stones as they pass by. Here the Bey halted; but as the rain was still pouring down, I invited him to take shelter in my tent, gave him a seat upon my bed, a pipe of Latakia, and—a cup of coffee.

My distinguished guest spoke French fluently. After a few hours the sun broke forth out of the western cloud-banks, and poured a flood of splendour over the minarets of Omar and Olivet. The red masses, brilliant and sanguineous, went flying eastward to the wilderness, and the day went down, calm and clear, and beautiful, and I still sat talking with the best of Pashas and the most gentlemanly of Turks.

With true oriental politeness he never alluded to the object of his visit. But I had divined it; and to gratify him brought forth my portfolios and displayed the precious fruits of my photographic labours since my arrival in Palestine. He eagerly scrutinised every picture, and after careful inspection, pronounced the name of each, and when I bowed in token of assent, his bright eye sparkled again, and the shadow of a smile played around his mouth. This inspection over, I planted my camera at the door of the tent, and with the aid of a mirror let him view the mimic scene. He was lost in wonder and admiration, but could not divest himself of the idea that the objects themselves were in the box. And when a living object crossed the field of view, his perplexity was extreme. *Mashallah! Mashallah!* he cried, God is great! I endeavoured to explain to him the nature of the instrument and the *modus operandi* of taking a picture; but as it was growing too late in the day to make an experiment, I invited him to come again in a few days, when I would go through the ceremony or incantation, as he called it.

I had made a friend of the Pasha. He evidently regarded me as a superior being, having powers till then unheard of in my hands. He took his departure with many expressions of friendship and oriental compliments, which in modesty I cannot venture to pen.

The Bey was punctual in his visit to-day. He came with troops of friends and retainers, and I have had a pretty hard day's work of it. I had made extensive preparations; and among other items, was fortunate enough to procure a basket of champagne. It happened to be our gracious Queen's birthday, and I resolved to celebrate it after a fashion of my own. My photographic operations were watched with intense eagerness — nay, with awe. My guests evidently expected an explosion from my camera, and kept at a very respectful distance. Business over the fun came next in order. It commenced by letting of some Chinese crackers, which created an immense diversion, but so alarmed my faithful Hassan that he threw himself on the ground in a state of collapse. John proposed that he should be revived with a glass of champagne, which being duly administered, soon produced the desired effect. He asked for another, not with his tongue, but with his eyes, and it seemed to agree with him so well that we administered half a bottle. We had not calculated its effect upon Hassan. He soon grew uproarious, and performed some very singular antics which so amused the Bey that he laughed until the tears ran down his beard.

I had provided a dinner for my guests. It was served with the addition of wine. The Bey had been in England, and understood "dinner," and when his health was drank responded in an elegant and complimentary speech. It was a curious scene. His officers and servants crowded around, and watched with wistful eyes, the wine disappear down our irreligious throats. But perhaps I ought not to call it wine, since they did not. For some reason or another champagne is considered by most Moslems an allowable drink, and many worthy and intelligent men, like my friend the Bey, who strictly refuse ordinary wine, drink champagne and sometimes brandy.

The Bey is a keen observer of men, and though he drank freely there was no one of the party less affected by the wine than he. Polite, affable, and dignified, he was at the same time full of the spirit of the occasion, and was polite enough to say that he would like to dine in the company of Englishmen every day.

While our little drama was being enacted beneath my tent a critical episode was taking place outside. An extra half-dozen of champagne, set aside as a reserve, had been scented out by the Bey's scribe and the Cadi who accompanied him: they helped themselves, and I am sorry to say got most uproariously drunk. The Bey was chagrined and angry at this breach of decorum on the part of his staff; but John smoothed the matter over, and took upon himself the rather difficult task of seeing the representative of the clergy of Islam to his tent in safety.

I could not help laughing to see John helping the Mohammedan clergyman along that evening. The worthy Turk depended heavily on John as he swung along, muttering sentences, not from the Koran, but such as would have subjected him to a fine from any British magistrate. But it was our Queen's birthday!

Coffee was served, and we smoked and talked, and the hours sped along. And how swiftly the hours fly over these Eastern skies! Life seems not half long enough to enjoy wandering up and down the hills over which I have been so long a rover.

With the night came silence! In the moonlight we walked down the valley. The fountain at the pool of Siloam murmured pleasantly, and we sat down beside it. A troop of Bedouin horsemen came dashing up the valley, and paused before us. The leader sprang to the ground as he recognised my guest, and pressed the Bey's hand to his forehead and his lips, then silently

remounted and rode on. An owl flittered in the air overhead, and soon sent his sharp scream down from the caverns near Siloam village, across the valley; a dog on mount Zion answered with a bark, and the shrill cry of jackals above us on the hill of Acaldema rang up the valley of the sons of Hinnom. So the nights of these later years pass with the cry of the owl and the wail of the jackal over desolate Jerusalem.

The day's fun is over; the tents are closed, and the Arabs lie sleeping in the night air around. I am the only living object moving about. All is silent and calm. I retire to my tent reluctantly, for there is a charm over the scene from which I can hardly tear myself away; but the air is chill, and I know not what ill effects it may exercise upon my frame not yet inured to the climate.

P.S. — Mohammed Bey has a head-ache this morning, and is a little repentant, as most people are after "dining out." I went to his tent to inquire after his health, and we renewed our vows of eternal friendship over a cup of coffee. In my travels through life and the land of the Philistines, may I meet with no worse acquaintance than Mohammed Bey; I can hardly hope to meet a sincerer friend. May his shadow never be less! D. T.

Practical Instructions on Coloring Photographs.

By Alfred H. Wall.

CHAPTER V.

COLOURING WITH DRY OR POWDER COLOURS.

Daguerreotypes and glass positives are generally coloured by a very easy process with dry brushes and powder-colours, by the aid of which some of our more skilful operators produce effects closely allied to those of coloured crayons.

The method of manipulation is so very simple that, save in the selection of tints and colours, there is not much to teach, and consequently not much to be mastered by the pupil in the shape of mechanical difficulties. Until very recently, powder-colours were prepared with so little reference to the surface to which they were intended to adhere, that this branch of photographic colouring occupied a very insignificant position; and the only directions of *a practical nature** that could be given for their use were simply to *dust* on a little pink or flesh colour here, and *dust* it carefully off there, blow it gently to remove the *very* loose particles, and—that was all: the powder once on in the form of *dust* of a certain colour could not be retouched, because every attempt to add more colour merely removed that already applied. Under these circumstances, it was only colourists who prepared their own pigments with a knowledge of the peculiar requirements of this process, and the means of meeting them, who were really successful.

Now, however, if the amateur meet with such difficulties it is his or her† own fault; for although bad powder-colours are very extensively sold, some of our best colour manufacturers have undertaken their preparation, and thus bestow a really artistic power in their application to the collodion or metal surface. M. Mansion, the first of our colourists in this branch, has advertised his colours for some years. Mr. Newman has also produced a very excellent set of colours, and more recently such colours, with peculiarly attractive qualities, have been introduced by Messrs. Reeves, of Cheapside.‡ I find in practice that the colours of Mansion and Newman are best applied before and after varnishing; but those last named do not require this, as the simple act of breathing appears to fix them sufficiently for the reapplication.

THE MATERIALS.

The colours are sold in small bottles, and their tints and shades are indicated by names (suggestive of their use) and numbers. If a box of these be purchased it will be provided with a set of earthenware saucers to contain the colours, or a palette of velvet for the same purpose, brushes, gold and silver shells, &c.

The brushes or pencils should be carefully selected In oil or water a somewhat inferior brush, being aided by moisture, may do; but the dry brush will not retain its point unless it be of good material and carefully made. As softness is one of their most desirable qualities, the *dark* and not the red French sables will be found best. They must be carefully preserved from dust, well rinsed after use and pointed with the lips before being put aside to dry. It is desirable to keep a good supply of brushes, as they soon lose their fine point when in use, and this can only be recovered by moisture, after which they are not again fit for service until *perfectly* dry. A camel hair brush, called a "duster," will also be required.

The blower — An Indian-rubber bottle with an ivory mouth-piece, used to remove loose superfluous colour.

Varnishes, &c. — A varnish prepared expressly for the reception of dry colours should be selected, as very few indeed of the ordinary varnishes (if any) take the powders well, being too hard and smooth; that sold by Henry Squire and Co., for the alabastrine process, is one of the best varnishes for colouring upon that I have met with; but a solution, not a varnish, sold by Messrs. Reeves, holds the colours firmly — indeed, for those who desire to *colour* highly, nothing can be better. A black varnish is sometimes used for "backing up" the glass positives, the principal effect of which is the utter destruction of depth and transparency in the shadows, the changing of the purest whites into a leaden grey, and the imparting of a dull, heavy, and metallic appearance to the whole picture: such a photograph will *never colour well.* The best material for "backing up" is a dark maroon velvet, which having depth in itself *and colour*, is no small assistance both to the photograph and the colouring. A solution prepared as follows has been strongly recommended by some professional friends, but I have never tried it: — put a little Canada balsam into a bottle with some spirits of turpentine, and allow it to stand a day or two; shake well, and add about 13 drops of it to one ounce of spirits of turpentine in another bottle; mix well; filter (with blotting paper), and apply it as you would collodion (viz., by steadily pouring into the centre of the plate, gently inclining it to and fro until the whole surface of the positive is coated, and then pouring back from the corner opposite that it is held by); dry with heat. Should the colours bite *too* quickly, add a little more turpentine to the solution.

THE FIRST COLOURING.

Your picture duly selected (and if you use Messrs. Reeves's solution, as I do myself, duly prepared), select a clean, well pointed, and *quite dry* pencil, take up very little colour, and apply it with a *gentle* rubbing motion in a circular direction. As is usual commence with —

THE FACE.

Take up the pale orange, or the "horizon tint," and mix with a little white: with this colour (a pale, warm yellow) strengthen the high lights (see maxim 40) which will be found upon such portions as are most prominently exposed to the more direct rays of the light, such being of course the top of the brow, cheek bones, the nose, and chin, upon the lighted side of the face: soften this into the "local" tint of the flesh, which may be represented by either of the prepared "flesh tints," with or without the addition of a little warm brown, orange, or carmine, as the complexion to be imitated may determine. Darken the local tint as you approach the half-tones, carefully avoiding the *darkest* shadows, which *the powder colours always destroy.* Where the skin is thin the blue veins will tinge the flesh with their own colour, therefore touch a little pale blue upon the corner, between the eye and nose, the temple, &c.: a stronger blue, green, or purplish grey, if your subject be a man, may be required about the upper and lower jaw. With careful touches colour the lightest part of the upper lip with a little crimson, and that of the lower lip with pink, No. 1, finishing it with carmine. If the eye be blue or brown, put a touch of either colour, *with extreme care*, into the iris diagonally opposite the "spark" or gleam of strong light in the eye (see maxim 45). Should the hair be light, a little of the requisite colour may be worked over the lighter portions.

Letters to a Young Photographer.

No. XIX.

My dear Eusebius,

If I were not satisfied that you possess the sixth sense I spoke of in my last, I should not trouble myself to proceed any farther in disquisitions upon Art and Nature. But as I know you are an artist born, and eager to study the principles of Art, let me, who have groped my way through darkness and discouragement to something like clear views upon this subject, hold up a torch, as it were, to you who are but now starting on your journey,

* Many writers upon this subject, in their ignorance of the manipulatory difficulties have given their readers instructions copied from works upon miniature and portrait painting, which. although very good in themselves, were curiously impracticable with such appliances as powder-colours and dry brushes, and must have sorely bewildered all who essayed their skill under such guidance.

† Most of the professional colourists in this peculiar branch are ladies.

‡ The new "Absorbent Photographic Powder Colours."

and haply I may prevent your falling into many bogs and quagmires into which the *ignis fatui* will lead you, if you follow their light "that leads astray."

I do not arrogate to myself any special knowledge on the subject, but have studied much, and, sorest of trials, had to unlearn much that cost time and labour to learn. I have sought to learn many things, prove all, and will now hold fast to that which is good. Art-teachers I have generally found to be blind teachers of the blind. For a long time I looked around for a set of principles upon which a sure foundation might be built. I was presented with a host of unmeaning phrases — mere words, the senseless echoes of forgotten axioms. With us Art is an exotic; it comes to us from other and more genial climes, and suffers greatly in the transit. For the most part, our Art is sunk into a process of mere manufacture. Our pride is greater in the past than in the present. Few amongst the present race of artists are worthy to wear the mantles of fame and honour, worn by our Gainsborough and Flaxman. Few of our artists can draw well; still fewer can colour naturally. Undeserved encouragement and blind patronage have fostered exaggeration and conceit. And the British school of Art, in this middle of the nineteenth century, has no better representatives to hold up to the admiration of posterity, than the so-called pre-Raphaelites, who might just as reasonably call themselves pre-Adamites.

But I must proceed with the burden of my song, my symphony being quite long enough. I have struck the key-note, and you may anticipate what you are to expect.

The beautiful, and by the beautiful I also understand the good and the true, is the province of the artist's labour. When the artist justly appreciates the nobleness of his mission, he paints only the good and the true. Woe to him if he deals only in shams: if he sets up ignorant formality and blind conventionality for Nature and her truths! If he would be great he must study Nature. But how shall he study Nature? what are the means? which is the method? where is his guide?

I begin to feel the magnitude of my presumption in attacking this momentous question; but having picked up a few crumbs that fell from my master's table, I proceed to share them with you.

We are sometimes told by those who discourse on Art, that the object of Art is imitation. But if we go farther, we learn that imitation is the lowest form of Art: it being the means and not the end. When an artist paints a noble head or beautiful landscape, he does not imitate the skin and hair, the sky and water, but he *represents* them. Art is a representation. If the aim of the artist in copying Nature was strict imitation, it would be as much as to say that the highest degree we can attain in Art is to deceive the eye; but to deceive is one of the lowest steps. Art operates, it is true *by* imitation, but not *for* it; it is the instrument of its conceptions, which has only to be true and faithful, but it is neither the result nor the limit. Nature, the source of all imitation, furnishes the elements, but it is Art that combines them. In Nature these elements are vague, scattered, and confused. Art selects and arranges them. Nature presents beauty in scattered fragments. Art collects and assorts them. Nature is dumb and inert matter. Art clothes it in thoughts and gives it a language.

The artist desires to represent a given object upon paper or canvas. This object is a solid body, and like all bodies, has three dimensions, and we desire to represent them on a body that has only two. What means shall we employ to attain this end? Three, and no more:—outline, relief, and colour. But these three means may be reduced to two; for in painting we can represent objects by form and colour only. Now outline and relief are the two elements of which the imitation of form is composed: they differ in their nature and also in their method; and in the analysis of imitation as a means we must consider them apart.

We will first compare these three means of imitation together, and then study them separately, acquiring a clear idea of each.

The outline is that line by which I define the space occupied by the object to be represented. In proportion as my eye follows the contours my pencil traces them on the paper. So far as the conveying of an idea of the object is concerned, the outline is all-sufficient, and we may dispense with relief and colour altogether. You may see the power of outline in the hands of a master by turning to the "outlines" of Flaxman, every one of which is as completely a picture, in the sense of a picture being a representation, as if it covered an acre of canvas painted in the most glowing colours. Let the painter labour as he may, he cannot with the most elaborate pains produce a *greater result* than he can by the merest outline. But the outline must be traced by the hand of a master.

But there is a host of forms which we cannot put on paper by means of mere outline, such as, for instance, those which express projection. To represent all the modifications certain bodies contain we must have recourse to relief, and give additional touches to my drawing in outline to render it a true imitation of a solid body, I obliterate the outline altogether; and yet of the three elements of imitation it is the most important of all. Outline represents essentially the character of the object: relief, concurring to the same end, does not bring so many elements, or concurs only in a secondary manner.

Colour is the lowest means of imitation. It is surpassed by the other two; it is nothing without them. In fact, many imitative arts content themselves with the first two means: sculpture, for instance, which employs contour and relief, and expresses everything by form and nothing by colour. The Laocoon is white, yet it respires, suffers, groans. The Venus de Medici, despoiled of her fresh and delicate colours, is beautiful, voluptuous, and modest.

It is the same with engraving, chiselling, drawing in India ink, and in photography, which act through form and not through colour. From this it results on the one hand that colour alone is powerless to imitate, while on the other it is necessary to a complete imitation.

We may by another way discover which of the three concurs most to the highest results of Art, and here again outline appears to be that one.

The highest results of Art — "high Art"—are those which represent the character, expression, and emotions in man and other animated beings; those which transfer to canvas tenderness, anger, remorse, shame, and revenge; those that depict life and action.

Now in representing these things outline is all-sufficient. Before the colourist had applied his swarthy tints, the outline had informed me that this man was a robust African, by the form of his face, by the curling of his hair, by the height of his cheek bones; his country was known to me, his savage energy displayed. Before those pale and livid hues had combined to interest me in behalf of the dying Dido, already had the outline revealed to me the drooping eyelids, the half-closed eye, the depressed eyebrow, the weakness of her arms, her langour, her expiring mouth, the last sighs of this forsaken lover. Before the fire and magic of the pencil had animated this scene of carnage, already, by the aid solely of the crayon, I had seen the mettled coursers, the disordered lances, the rushing of battalions, the terror of the fugitives, and the agony of the dying warrior.

The idea I have of the part which each of these means plays in a composition of the kind I speak of — "high Art" — is, that outline, aided by relief, speaks directly to the heart, mind, and soul — to whatever is elevated and noble in our nature. Colour flatters the eye beyond every thing, and deludes it also; it excites the imagination, it unites with the poetical, but rarely penetrates the heart.

In proportion as we descend from "high Art" to Art of a lower grade, outline and relief are diminished in importance, and colour gains advantage. In a landscape, colour, next to good drawing, is every thing: here the passions, action, or life have little or nothing to do. If you imagine this landscape, or rather *sea*-scape, reduced to the representation of a clear sky and calm sea, a single line, drawn with a ruler, to represent the horizon, forms the picture — all the rest belongs to colour. Imagine all the intermediate conditions, and you will come to see that the relative importance of colour increases in proportion as the nature of the composition departs from the region of "high Art."

These truths are so simple and self-evident that it would appear idle to mention them; nevertheless they are but little appreciated, and I think but little known, although they are the basis of all just appreciation of the imitative arts.

It is a curious fact that, of the three means of imitation, outline, the most excellent, is of the three the only conventional one; it does not exist at all in nature, and disappears in the complete imitation. Outline is an aid, nothing more — a thing that exists only by convention. By it we express the limits or boundaries of the space the object occupies, not only because this limit is so expressed in the model, but because we have no other means of expressing it.

However arbitrary and conventional it be, its power is none the less real. It speaks most to our intelligence, because it traces artificially that which first strikes the attention in every object. Before remarking on the colour of a shield, or the relief of the chiselling that embellishes it, I have already observed if it be round or square. Before noticing the bright plumage of the bird, or the graceful roundness of its form, I have previously observed that it has only two feet, while some other animals have four.

And this distinctive character—that first seized upon by the understanding—is not the relief, nor the colour, but the external contour, the outline, and it is all-sufficient.

Outline, then, is an artificial means of imitation; but it responds so well to our intuitive method of observing, that of the three it is the one which most rapidly proclaims things to the evidence of our senses, and most spontaneously recalls objects to our memory.

Colour is more in relation with the feelings than with the understanding, and that is why it acts upon animals more than upon ourselves, because, having the same feelings as ourselves, they have not the same intelligence.

In my next I shall speak of these three elements of imitation, outline, relief, and colour, in their complex relations, giving rise to what is termed "chiaro'scuro." We shall then be prepared to consider what position Photography holds in Art, as a means of representation.

Photographic Glossary.

Sugar — A name given indiscriminately to all bodies possessing a sweet taste, but especially to the sugar of the cane and of the beet. In chemistry this name is reserved for substances that possess the property of undergoing fermentation. Sugar of milk is sometimes employed in photography as a substitute for serum: it forms hard, white crystals, which are slow and difficult of solution in cold water.

Sulphate of Iron — There are two sulphates of iron: the sulphate of the protoxide and the sulphate of the peroxide. The first is familiar under the form of green vitriol, or green copperas, the crystals of which are soluble in twice their weight of cold water. It is a useful developing agent in photography, especially in producing positives on glass.

Sulphuric Acid — Commonly known as *oil of vitriol.* It consists of one equivalent of sulphur united with three equivalents of oxygen, and one equivalent of water. Its specific gravity is 1·84. It is a very powerful acid, and largely used in the arts. To the photographer it is valuable in preparing gun-cotton.

Sulphide of Silver — A compound of sulphur and silver, produced whenever metallic silver, or a salt of silver, is put into contact with hydrosulphuric acid, or a soluble sulphate, or certain bodies containing sulphur which are readily decomposed. Hyposulphite of soda forms sulphide of silver when mixed with the salts of that metal.

Sulphur — A well-known elementary body, which forms many important compounds when combined with other bodies, as sulphuric acid, the sulphates, hyposulphites, &c.

Sulphur-toning — Positive proofs may be toned by the action of the sulphur contained in hypo-sulphite of soda, in lieu of chloride of gold. When carefully performed, tones equal to those resulting from the use of gold may be obtained. The process is described on page 61.

Tannin, or Tannic Acid, is obtained from gall nuts, oak bark, &c.: it is the type of astringents. It is usually met with as a pale yellow powder; very soluble in water and in weak spirit of wine. It possesses the property of precipitating gelatine from its solutions, and of combining with it to form a leathery substance. On this account it has been employed in photography in varnishing proofs with gelatine, and then acting upon the gelatine with solution of tannin.

Tartaric Acid — This acid is contained in the juice of the grape. It has of late occupied a conspicuous place in photography, in connection with the experiments of M. Niẽpce de St. Victor on the action of light.

Tartrate of Silver — This salt of Silver is at first only feebly acted upon by light, but after a time it grows darker under the influence of that agent than any other salt of silver, on which account it would appear to be admirably adapted for positive proofs. But its want of sensitiveness is a bar to its use.

Taupenot's Process — A process in which the glass plate for negative pictures is coated both with collodion and albumen. It is described on page 204.

Test Paper — Bibulous paper stained with the blue tincture of litmus. It is reddened by acids; the blue colour is restored by the action of alkalies. It is indispensable to the photographer.

New Books.

How to take Stereoscopic Pictures, including a detailed account of the necessary Apparatus, and a minute description of the Collodio-Albumen, Fothergill's, and Powell's Dry Processes. By Wm. Ackland. Third Edition.

(London: Simpkin, Marshall, and Co.; Horne and Thornthwaite.)

Although nominally a third edition, there is sufficient novelty therein to entitle it to more than a casual notice. It is not intended as a mere introductory book for those quite unacquainted with the photographic art; but though entering into sufficient details to render it intelligible to photographers who have only as yet passed but a little beyond the threshold towards the higher mysteries, it contains very succinct and intelligible directions not only for producing stereoscopic negatives, but also for printing them as transparencies, &c.

There is also a choice of three dry processes offered for the selection of the amateur, all the necessary particulars being clearly given for their successful practice, and the happy medium of sufficiency without redundancy of information attained.

Powell's dry process appears to be founded on the use of a more than usually sensitive collodion of a contractile character, with a solution of glycyrrhizine as a preservative agent; but as this is not an easily procurable substance in a pure state, and the time of exposure in the camera does not appear to be shorter than for Fothergill's process, we scarcely perceive in what its advantage consists. Probably, however, those who have tried it, which we have not, may have discovered that some does exist, and Mr. Ackland asserts that the results obtained thereby are superior to any of his former productions.

Glycyrrhizine in an impure state, in the form of an extract from the liquorice root, has been used in America for the same purpose, as indicated some months back in one of our leading articles.

Irrespective of the performance to the letter of the promises held out, there are several useful hints available in many branches of photography in general; and the book may be safely recommended as an unpretending but useful little guide.

Foreign and Colonial Correspondence.

Paris, September 10, 1859.

The researches of M. Niẽpce de Saint Victor form a standing topic for photographic discussion and commentary; and if he be denied the honour of being regarded as a discoverer, few will deny his right to the title of *fermenter.* What he has said and done has certainly put the photographic world into a state of brisk fermentation. In so delicate and complex a subject of investigation as the chemical action of light, it is easy to build and easy to overthrow. In seeking to give explanations of certain phenomena, the last holds good until it is refuted by a new one, which in its turn is refuted also; so that in fact we never know where we are, nor whether we may abide by what we fancy we know.

The results obtained by M. Niẽpce are attributed, first, to the action of light. Light had something to do in producing them, without doubt; but as the same results can be obtained by the agency of heat without light, why of course it is not light, but heat. You may stop there and take breath, for a gentleman is coming along who proclaims your notion as stuff and nonsense; he can produce the same results without either heat or light—in a refrigerator—by electricity. Well, we will stop here, if you please. Oh no; you must move on, for here comes Professor Ozone, and he does not care a fig for your light, nor your heat, nor your electricity: he has got something in his pocket. Well, and so has another—formic acid. Beat that if you can. But what shall we do with the gentlemen who talk of the formation of glucose, and of the green salt of uranium? Oh, let them wait till they can explain the following experiments:—

1. Take a black and white feather and expose it to the sunshine, then apply it to sensitised paper: only the white portions will impress their image. It is the same with black and white chalk or marble.

2. Pipeclay or freshly broken porcelain, exposed to the sun's rays, and afterwards applied to sensitised paper, blackened it in the parts exposed to the sun, while the non-insolated portions produced no effect.

Many of the experiments made by M. Niẽpce have been repeated in pure hydrogen and in a luminous vacuum with the same results as in the open air.

Now it will not be easy to explain the above experiments by the solutions hitherto proposed, and we may still maintain that the phenomena of the action of light remain unexplained.

The following experiments have recently been made by M. Nièpce de Saint Victor. Two pieces of cardboard were impregnated with a solution of nitrate of uranium: one piece was put in the sunshine, and both were placed in tin tubes; then the tubes were filled with liquid starch, and at the expiration of forty-eight hours the two solutions were tested by M. Bareswil's test. That which had been in contact with the solarised cardboard gave a slight reduction of a salt of copper, and that which had been in contact with the non-solarised cardboard gave no result at all—not even a change of colour.

An experiment still more conclusive, consists in filling a bladder with starch, and suspending it in a tube containing a solarised cardboard. The result is the same.

These experiments clearly prove, that when we envelope grapes in a paper bag impregnated with nitrate of uranium, nitrate of iron, or tartaric acid, the fruit ought to mature more promptly, and contain more sugar.

Wine exposed to the sun in a glass bottle, hermetically sealed, acquires a different taste than when exposed to the sun in a metal vessel. It is thought that new wine may be ripened by exposure to the sun.

It is probable that if the wine were put into a blue or violet bottle, the action of the light would be more energetic; it would also act more favourably upon red wines than upon white.

M. Nièpce de Saint Victor has recently invented a curious and ingenious instrument, which it is expected will render important assistance in researches upon light, and is very curious in a scientific point of view. It is a *solar-pile*. Its composition is very simple, consisting of a disc of copper and another of zinc, separated by a disc of cork, and furnished at the upper extremity with two copper wires which meet together. This is plunged into a solution of nitrate of uranium and oxalic acid. Under the influence of the solar rays the liquid becomes agitated, and enters into what may be called a state of ebullition in consequence of the disengagement of electricity. The zinc is sensibly attacked and forms a precipitate, which M. Nièpce thinks is oxalate of zinc. It remains to experiment with this pile, which will be more economical than any other. J. P.

Geelong, Victoria, May 14, 1859.

Sir,—I have received only two numbers of The Photographic Journal out of five this year. In consequence of its being a semi-monthly, the number for the 15th is usually omitted. I would suggest that, for foreign circulation, they should be put up in monthly parts. The change of name deprived me of the February number, the Society's Journal having been sent in mistake, in consequence of its editor having adopted a similar name to your own. You kindly refer me to page 206, but that is in a missing number.

I am glad to see that, since your visit to the "land o' cakes," you are getting a little into my way of thinking about long focus lenses. You can inform Mr. W. Housley that, if the front lens of a half-plate combination is not long enough in focal length, he has only to take it out and employ the back lens, removing the middle ring, and turning the plane face towards the object, use a suitable diaphragm, attaching it to a tin camera with a pair of double backs, and he will have an excellent achromatic view lens of long focus. At least mine was, that I sold to buy a crown grant for 13½ acres of the Ballarat Gold Fields, which is no doubt the best speculation that has been made with a half-plate camera. And the same lens, mounted in a tin tube with a good eye-piece attached, will make a splendid telescope.

I see that you accuse me of ignorance for proposing a non-achromatic lens. I have only to remark that I am as well acquainted with the theory of optics as most persons who have not reduced it to mathematical calculation. Your remark in the Glossary, "it is even asserted that it is impossible to make the chemical and visual foci coincident, except for one given condition," rather proves my statement to be correct, coupled with the proof in the pictures, and we have a way here of judging the quality of kangaroo tail soup by its flavour.

I am glad to find large pictures are being taken with long focal length lenses, and have no doubt that dry plate negatives can be taken instantaneously and reduced as quickly as a positive portrait in the wet way, and from my experience say as well.

Next, I have to remark that our motto is "Advance, Australia!" but in the "Letters to a Young Photographer" the writer has omitted M. Gaume's gutta percha process, which, in my opinion, is the greatest discovery in paper photography since Mr. Jordan's application of the rod and the double iodide solution, and will, I think, make glass quake for negatives, its advantages are so great: first, the paper does not buckle under the rod, it dries in a quarter of the time, the pictures are on instead of in the paper, and the outlines are sharp; it allows the nitrate and hyposulphite to be washed out easily; in fact, it's *the thing*. But the benzole must be well *dried out* before the albumen is applied.

Next, I wish to propose to the photographic world the use of india rubber instead of gun-cotton, a desire being expressed for some other substance. I took pictures with it in the year 1850. I dissolved it in benzole, but it would be better no doubt in ether, and it has been added to collodion and found to answer for surgical purposes, I think it may answer for astronomical and microscopic pictures.

I also wish to propose the use of the fluoride of silver as a bath. Many years ago it was introduced as an accelerator, but from its properties I think it was not used rightly, the salts with which it was associated are not soluble salts, viz., iodide, bromide, chloride, &c. Hardwich says it produces a soluble salt with silver, and if so it dissolves out,* it should therefore be used as a bath. Some photographers have solicited ideas, I throw out this one, and if it be approved I shall be glad to receive communications on the subject of the *modus operandi* pursued. I propose to use in atomic proportions fluoride of soda or potassium and nitrate of silver, as a bath; a field is then open for investigation as to the insoluble salts best in the collodion, as it is not probable that the same salts as are used in collodion for the nitrate bath would be applicable to the fluoride bath.—I am, yours, &c. ANTIPODES.

[Not so fast, good friend; our opinion being based upon some knowledge, practical and theoretical, of optical matters, is not so easily changed, in fact it remains just the same as before. In a *well-constructed* portrait lens, the back combination ought not to have any plane surface, but should consist of a bi-convex crossed lens of crown or plate-glass, and a concavo-convex of flint glass, the concave side being turned towards the convex lens. Now, by a removal of the ring, it would be impossible to bring the concave side of the flint lens outwards; and in fact it is totally unfitted for landscape purposes, by which observation we do not mean to assert that no picture can be taken by it, any more than we did with a non-achromatic lens, but simply that *good pictures* cannot be taken therewith as a rule, and never equally good in all respects as *can* be obtained by a lens specially constructed for the purpose. We have an English motto, "slow and sure," and we have had no *glass-quake* here. The conversion of the free nitrate of silver into a fluoride has already been proposed, but the method suggested by our correspondent is inapplicable.—Ed.]

Correspondence.

☞ **We are at all times willing to assist our Correspondents to the utmost of our ability, but we can only do so through the medium of the Journal. We cannot give private replies except to personal friends.**

EXPERIMENTS IN PARALLEL DIRECTIONS.

To the Editor.

Sir,—Charles Lamb, if I recollect rightly, in one of his admirable "Essays of Elia," categorised mankind into two great classes, "those who borrow and those who lend." Had the "gentle Lamb" lived in these days of photography, and perused the pages of The Photographic Journal, we can almost certify that his pen would ere this have produced some amusing articles on photographers in general, and we could venture to guess under what facetious title the present number might have elicited his good humour.

Though Charles Lamb has long slept with the dead, his classification remains for our edification, and it appears in daily life we must succumb to the division; but when a man finds that he is reckoned in the first class, and knows that he is thereby personally wronged, he must either sit quietly under the error, and say, with the Turk, "Allah kerim!" or attempt to recover from his false position. Most, I believe, whose hearts are not wholly wrong, endeavour to state their justification before their friends. In my own case—thanks, Mr. Editor, to you—so able a defence has been already set up that it is scarcely worth an attempt to strengthen the position; and I certainly should refrain from occupying a space in your Journal, if there were not such a *personal* accusation and misstatement in the letter of your correspondent, signed "C. J. Burnett," that to let it pass without remark would be tantamount to admitting a charge of gross plagiarism. I can hardly suspect that the gentlemanly and polite

* Fancy adding nitrate silver to the bromide, iodide, and chloride, as an accelerator; it is a case in point.

rebuke contained in Mr. Glaisher's reply, published in your Journal of August 15th, and originated under almost similar circumstances, has been perused by Mr. B; but if so, it has signally failed to conduce to his equanimity of temper. Old habits are not so easily changed as our garments, and a brush on the latter may remove the dust, but the stains remain.

It seems that your correspondent is determined to walk the world alone, or to dispute indiscriminately with those who take the same path; and his surface appears to have become so irritable by the fumes of the laboratory, that both Mr. Hannaford and myself, quite unintentionally, have deeply tested its sensibility, and which, from the developing liquid used by Mr. B. containing some impurity — perhaps in the *acetic acid* — has stamped a strong image of our labours, though in my case over-development has somewhat fogged and stained the picture; so that neither on the ordinary printing paper, nor, I fear, on "uranium" prepared, nor any other "allied" papers; nor by any other "allied substances," nor by any other "allied processes," is the print preserved with the lights pure, the half-tones harmonious, the shadows soft: in fact, the tone is faulty and the picture sadly defective from its want of truth.

Mr. Burnett accuses me of having filched from his pamphlet the recommendation of paraffine, &c., *vide* p. 212 of last number. Let me, for my own justification, positively assert, on the veracity of a gentleman, that to my best belief *I have never seen nor in any way made use of his pamphlet;* indeed, from the style of the articles lately sent by him to your Journal— and the graceful tone of the letter and its lengthened postcript — I should be induced to studiously avoid ever ordering the same from my bookseller, even at the risk of occasionally experimenting in parallel directions with him.

The use of paraffine oil arose thus:—Passing, about the end of June *last year*, in Regent Road, a shop, then lately opened for the sale of lamps and paraffine oil, and knowing something of its properties, I walked to the nearest chemist's shop, purchased an empty bottle, and returned for some of the oil. It was at once tried in various ways for photographic purposes, and eventually used as stated in my first communication — its disagreeable smell having also suggested the addition of benzole. I have many negatives taken shortly after. Now this does not quite rest only on my own veracity, as several friends used to see the results. On entering the house and approaching my working room, they used to say, "O there is Maddox at his photography again!" from smelling the paraffine some steps away.

In that process, among others, I also employed for sensitising, the formula recommended, as far as my memory served, by Mr. Sisson. This was noted in my communication to you, and, if needed, might be employed as a further argument that I am little desirous of detracting from any man's merits, not even from that of the author of "allied substances." What is the truth of the matter as set out in your Journal? —I have no other guide.—That I was using paraffine oil *ten months prior to the publication of the fertile pamphlet from which I am accused of abstracting without acknowledgment*, which, it appears, claims solid paraffine dissolved in alcohol.

Had I then rushed to your arms, you might have saved me, Mr. Editor, from such a painful weight of blundering, or being crushed by such a heavy chain of reasoning and invective. Had my experiments on the paper process begun yesterday, depend on it I should have hesitated to send you the result; but as they began in the intervals of an arduous practice abroad, shortly after the publication of Le Gray's *Nouveau Traité de Photographie* of 1851, they may save some of the imputation which, if couched in more gentlemanly language, would not have been ignored. If Mr. Burnett desires to preserve his labours intact for some posthumous work, silence should be his safeguard; or if he would be classed among those who like to enjoy the sunny side of a scientific reputation, let me try to persuade him to dip his pen in some one else's toning bath, and soak his papers longer in the cool waters of discretion, before he sets up as a photographic usurer, from whom we should all feel proud to borrow and pay with the interest of every honourable acknowledgment.—I am, yours, &c. R. L. MADDOX, M.D.

Woolston, September 1, 1859.

THE MAGIC LANTERN AND PHOTOGRAPHIC SLIDES.

To the Editor.

Sir,—Having a magic lantern, and wishing to apply it to photographic sliders, or rather they to it, I take the liberty of asking your advice.

The condensers are convex and plano-convex, three inches diameter. I have taken the front lenses out, and substituted a quarter-plate portrait combination, one and three quarter inches diameter. Not getting the resulting picture large enough, I next tried a half-plate lens three inches diameter, with I think worse results. I then took the front lenses out of each combination, with no better result. Is it compulsory for the condensers to be both plano-convex, and to be four and a-half inches diameter, as Mr. Hislop in a back number of The Photographic Journal recommends? The lamp is a patent Argand.

If you think I shall not succeed with the above condensers, do you think Mr. Hislop's is a good plan, and will it succeed in the hands of the non-genius? I am, yours, &c. J. R.

Liverpool, August 25, 1859.

P.S.—I have inquired the price of the two plano-convex $4\frac{1}{2}$ lenses; they are fourteen shillings. Do you consider the light strong enough?—J. R.

[The size of your condensing lenses is not of so much importance as regards quantity of light as area of the slider illuminated. With three inch lenses you cannot expect to use sliders of more than about one and three quarter inches square.

A quarter-plate portrait combination would answer well as an object glass, provided the room in which the lantern is to be used is *long enough*, but in an ordinary room there is not sufficient distance to give the requisite enlargement with such a lens, in which case it requires one of *shorter focus*, for you must remember that with a limited distance between the screen and object, the *largest* image is produced by the *shortest* focussed lens, as in a microscope; but bear in mind also that the amount of light is diminished in equal proportion. Direct your attention to obtaining a good light. If you employ an oil lamp, a lump of camphor dissolved in the oil materially enhances the illuminating power.—Ed.]

ANSWERS TO CORRESPONDENTS.

C. B.—Timon.—See our leader in the present number.

A. P. — You will be sure to get it at Horne and Thornthwaite's.

Medcalf.—See our article on the solar camera, and refer to the papers therein cited.

E. Strochan.—Your conjecture is correct. See answer to "A. H. B.," page 208.

Thos. Parkinson, Jun.—We cannot do so. Our time is too fully occupied to permit it.

Saml. Barkworth.—Thanks for your kind suggestion, but we prefer to be sought rather than to seek.

Amicus.—You can procure Mr. Russell Sedgfield's productions from Mr. Bennett, Bishopsgate Street Without.

J. A. Church (Norwich).—We strongly recommend a trial of the plan for paper photography published in our last. In our opinion it is one of great promise.

Subscriber (Colchester).—An over-acid bath produces a very *weak* picture, and demands a protracted exposure of the plate in the camera, in order to produce an impression at all.

Gin and Water.—We have had a "Windsor soap process" sent to us, but only in a joke from a frequent contributor; it was proposed as an infallible method of obtaining *clean* pictures; so that your "soft soap" would be "flat, stale, and unprofitable."

T. Allpress, Jun. — We have several times within the last twelve months given details of the method of working the honey process, which it would not be fair to our readers to repeat again; we must therefore beg you to refer back, when you will find all the information you require.

One who Approves. — We have always endeavoured to set forth the truth regardless of interest; in fact, we have no interest personally but in ascertaining truth. We are not, therefore, about to begin now to take a different course. We say with the knights of old, "God defend the right."

Robert Lomore. — Your experiment has most probably failed in consequence of your having performed it at *too low a temperature.* When a particular degree of heat is mentioned as a necessary element towards a successful result, it is important to consider *what scale* has been intended to be understood for the reckoning. Most French writers refer to the centigrade and not to Fahrenheit's thermometer, when alluding to temperature.

To convert one into the other proceed thus: —

Multiply the number of degrees on the centigrade scale by 1,8, and to the sum add 32, which will then show the corresponding degree upon Fahrenheit's scale.

Thus, $60° \times 1{,}8 = 108 + 32 = 140°$—so that you have been working at far too low a degree of heat.

To convert Fahrenheit's scale into that of the centigrade, of course the converse holds good, viz. — deduct 32 from the amount given and divide the remainder by 1,8.

Rationale.—It is supposed that the actinic rays effect a reduction, more or less, of the silver salt, by the abstraction of oxygen. The free acid yields a supply of oxygen, hence the difficulty of abstracting it from the silver salt in presence of free acid. It must however be admitted, that chemists have not sufficient real *knowledge* on the subject to speak with absolute certainty, and that much is conjectural of what is received as explanation.

To acidify a neutral bath of nitrate of silver for collodion *positives,* just sufficient *nitric* acid to cause litmus paper to become decidedly red is preferable — say about one drop of acid to ten ounces of bath; but for negatives, *acetic* acid is best in our opinion. In this case, if the test paper assumes a *warm purple hue* it is enough.

The nature of the collodion used should be taken into the account. Some kinds show an alkaline re-action, and these require an unusually acid bath; others contain free iodine, and then the bath may be neutral with advantage.

THE PHOTOGRAPHIC JOURNAL.

No. 103, Vol. VI.—OCTOBER 1, 1859.

In our impression of the 1st ultimo we directed special notice to the intention contemplated by the managers of the Art Union of Manchester, of giving as some of the prizes in the ensuing distribution bound volumes of choice photographs. Our attention has been drawn to the fact that there exist at the present moment two separate bodies, bearing designations almost identical — in fact, quite so in idea, the words being simply transposed. On reference to our remarks it will be seen that we regarded *The Art Union of Manchester* and *The Manchester Art Union* as one and the same association; but we learn with no little surprise that this is by no means the case: the former being that from which the advertisement published in our pages emanated, the latter being the original body, with which the Art Union of Manchester has no connection whatever. We learn, however, that Mr. James Law, the Secretary, who is responsible for the advertisement, was formerly connected with the original body. We know nothing at all about the particulars of the rupture, if rupture there has been; but our attention having been drawn by private connexions to the fact of there being "two Richmonds in the field," we consider it a point of duty to advise our readers thereof, in case any of them may have been inadvertently misled by our observations.

To an inquiry relative to the morality of a *double entendre*, it was replied, that "if a man means *well* the more he means the better." So say we relative to these two bodies; but at the same time we cannot but think that more good would be likely to arise from their union than their separation.

In consequence of the hints we received we have made inquiries relative to the position of the older association, and find that it is not in active operation this year, but that it is about being remodelled on a more extensive and permanent basis, and is expected to reappear next year under very favourable auspices, and with strong claims to support. We trust that photography will not be lost sight of in the new arrangements.

One of the manipulative obstacles alluded to by our contributor Dr. Maddox, in his recent paper, is that of obtaining readily an even film of albumen. A similar annoyance has occurred to others of our subscribers who have wished to procure albumenised paper by formulæ not commonly adopted, or on paper of a kind not usually kept in stock by the dealers in photographic materials: we therefore propose to throw out a hint or two relative to the preparation of albumenised paper.

Many photographers, amongst the amateur section, take great pains to procure new-laid eggs only: we believe this to be a mistake, and are convinced that ordinary shop eggs, provided they emit no offensive odour, answer just as well if not better. However that may be, the whites having been separated carefully from the yolks, without the membranes enveloping the latter having been broken — to insure freedom from accidental contamination with which, each egg should be broken separately in a cup — the requisite quantity of the albumen should be placed in a wide-mouthed clean bottle: one such as is employed for preserved fruits or pickles answers the purpose well enough.

To each ounce of albumen add ten minims of liquor ammoniæ, and also such quantity of chlorides, bromides, iodides, or mixtures thereof, as may be desired, they being first dissolved in water sufficient to effect their solution. Cut up a sheet of thick writing paper into small pieces about half an inch square, and put them also into the bottle with the other ingredients; the cork or stopper is then to be inserted, and taking the bottle in both hands, the contents are to be well shaken up for half an hour, or until the whole is in a state of froth. It is then to be allowed to repose until the following day, or at any rate for several hours.

An ordinary photographic dish being filled with the prepared albumen, by pouring it gently from the bottle into a glass funnel, having a piece of clean muslin disposed as a filter, and the beak of the funnel *resting on the bottom of the dish* to avoid the formation of bubbles, the paper is to be floated thereon in the usual way, and allowed to remain until the edges cease to curl up. The requisite time will vary materially with the kinds of paper used. English papers being generally harder and more stiff than the foreign kinds, owing to the difference of the sizing material, are easier to manipulate if held over a dish containing hot water *just before* floating, both sides of the paper being exposed to the influence of the steam for a few moments.

When the paper can be removed from the surface of the albumen without violently curling up, it is to be lifted by one corner and allowed to drip for a few minutes, steadying it in a vertical position by holding also the adjoining corner with the other hand. After dripping for about a minute from one corner, the hand that steadied the neighbouring angle to that by which the paper was suspended is to be gently raised, so as to become in its turn the suspending corner, which proceeding will cause the albumen to flow off from a different corner to that whence it first dripped, the flow being now at right angles to its former direction. After a few seconds — say half a minute — bring the corner next in succession to the highest point, and finally the fourth corner upwards, taking care that each one comes uppermost in *regular succession*, so that the drip has flowed from each of the four corners.

If the operation above described has been correctly performed, the paper will now be coated on the surface with an even film of albumen, scarcely flowing at all.

The great point to be aimed at is to *keep it* in the condition it now presents — that is, an even brilliant film; and to this this end rapidity in drying mainly conduces.

The American wooden clips are extremely convenient for suspending photographic paper while drying, particularly if a common pin be thrust at its upper end, through one piece of the wood of which the clips are made, and bent into the form of a hook.

By attaching two of these clips to a sheet of the paper, the whole can be suspended in a vertical position from a cord. By placing a couple of chairs, one on each side of the fire-place, and stretching a string from one of the backs to the other, a convenient line of suspension is formed. The paper should be hung with the *plain side* towards the fire, and as close as possible, so long as scorching is avoided. In about a couple of minutes the drying will be complete, and the surface should be smooth and brilliant, provided that the manipulations have been correctly performed.

We regret to find that a neglect of the usual courtesy of acknowledging the source of reprinted articles is apparently gaining ground in some periodicals. We were not a little surprised to notice in the number of *La Lumière* which was published on the 27th of August last, a translation, very slightly altered, of the paper contributed by Dr. Maddox, which had previously appeared only in our columns — our surprise not being excited by the reproduction of the paper, but by its being acknowledged as copied from the *Moniteur.* As the editor of *La Lumière* (a French photographic periodical) is always supplied with a copy of this Journal it is but reasonable to suppose that he must have been aware of the fact that the article in the *Moniteur* was not original, even if so professed. However, in order to prevent any question on the subject, we addressed a note to M. E. Lacan, the editor of *La Lumière*, drawing attention to the fact; but as he has taken no notice thereof, we presume that he approves the proceeding. If so we are extremly sorry that such should be the case, for we have hitherto regarded the publication in question as holding a position that such a course could only degrade.

We find also the same article copied into *La Revue Photographique*, but without any acknowledgment at all.

We fear that it is undoubtedly true that some English and American Journalists may have acted towards our French contemporary in the same manner as that of which we complain, but it is a proceeding that should be unquestionably discountenanced. An extract acknowledged is a compliment — unacknowledged it is an insult. What a pity that the omission of a few letters should be allowed to work so important a change for the worse!

From the numerous inquiries which we have from time to time received, both from professional and amateur photographers, for advice relative to colouring their productions, we cannot avoid being aware that the subject is one of considerable importance to many of our readers. Personally we have been unable to afford any assistance in the matter, being totally unaquainted with the practical part of painting; but we can scarcely regret it so far as our subscribers are concerned, because our own want of knowledge has been the cause of obtaining for them a more lucid and genuine set of instructions, as to the best method of proceeding, than has hitherto been published in any form. The more practical parts of the series are still in course of publication. The author is an artist of considerable reputation, actively engaged in the pursuit of his profession; and he has most liberally offered to enhance the value of his communications by affording advice through the medium of this Journal to those desirous of obtaining it, and criticism upon the essays of those who may be reducing his instructions to practice. To this end, specimens may be forwarded to Alfred H. Wall, Esq., 11, The Terrace, Walworth, accompanied by stamped directed envelopes for their return. As the necessary advice and criticisms will be published, it will be as well for each applicant to assume some pseudonym — for the truth unadulterated, though very wholesome, is not always palatable.

We are sure that all who have seen the productions of Mr. Wall will most readily appreciate the value of his advice and the generosity which dictates his kind offer.

OBITUARY.—Mr. ANDREW ROSS.

It is with sincere regret that we notice the decease of Mr. Andrew Ross, the well-known and deservedly celebrated optician, whose name is familiar not only to most photographers, but also to men of science generally, whose pursuits demand the use of optical instruments of a high character.

Our personal acquaintance with him commenced some sixteen or seventeen years ago, but his reputation was well known to us several years prior to that time.

Mr. Ross was not merely a manufacturer of optical instruments, but *an optician* in the most extended sense of the word; one who thoroughly comprehended the laws of optical science, and was as well versed in the theoretical as in the practical details of his calling. He was a clever mathematician, a cautious and careful observer of all phenomena bearing upon his occupation; not easily induced to adopt any novelty until he had well considered it from every possible point of view, and it was then only from a thorough conviction of its advantage that he finally took such into favour

He was slow in admitting the commercial importance of photography, hence he was not induced without considerable difficulty to embark in the manufacture of photographic lenses; and it was only by the continued perseverance of his son, Mr. Thomas Ross, that he was at last persuaded to bring his extensive optical knowledge to bear upon the subject.

To him scientific men are indebted for many valuable improvements in the telescope, microscope, and in the optical parts of photographers' apparatus. In his endeavours to overcome difficulties connected with any one of the classes of instruments named, he not unfrequently hit upon a principle specially applicable to another, and thus each in turn received benefit from his attention to those allied.

It is now about thirty years since he first settled in London, and his career commenced by his constructing a very accurate dividing engine, for producing the scales on astronomical and other scientific instruments. By the introduction of Mr. Solly, he constructed for Mr. Valentine a microscope of a much higher class than any that had been hitherto attempted — the optical parts consisting of doublets and triplets — and for this he received from the Society of Arts the Gold Isis Medal, and the sum of fifty guineas; but his great fame was due in the first instance to the excellence of his productions in connexion with the Achromatic Microscope, and the article "Microscope," in the *Penny Cyclopædia,* was written by him.

Early in the year 1831 a microscope was constructed by Mr. Andrew Ross, based upon the important discovery made by Mr. Joseph Jackson Lister, and communicated to the Royal Society in 1829, relative to the means of correcting the aberrations of microscopic achromatic objectives, and from that time the value of this instrument as a means of *scientific* research takes date. So rapid afterwards were the improvements he effected in the construction of microscopic lenses, that the errors of sphericity and dispersion were balanced to that degree of perfection that merely covering the object to be viewed with the thinest piece of glass (then about the two-hundredth part of an inch in thickness) was sufficient to disturb the corrections. This peculiarity was first detected by Mr. Ross; but he no sooner discovered it than he applied a remedy, the particulars of which he communicated to the Society of Arts in 1837, and for this important discovery and clever correction he again received from that body the Gold Isis Medal.

In the year 1837 Mr. Andrew Ross was again presented by the same society with the Silver Medal, for his invention of the Sphœrometer, an instrument adapted for the determination of the radii of curvature of lenses, especially of the smaller kind, these being by far the most difficult to ascertain correctly.

In the construction of refracting telescopes, whether for astronomical or terrestrial purposes, Mr. Ross was equally eminent, and his name attached has always been regarded as a certificate of excellence. In fact, some of Mr. Ross's astronomical telescopes have been said to surpass any others. In the production of these instruments he was assisted by his son-in-law, Mr. J. H. Dallmeyer, a native of Prussia.

It is however in connexion with photographic lenses that our readers will recognise Mr. Ross's chief claim to their regret, and rightly so, for from the very earliest rise of our fascinating pursuit he was in constant communication with those who have been the pioneers for smoothing and removing the optical difficulties that beset the paths of photographers. Many of those difficulties have been overcome altogether, some have been palliated, and others still remain to be vanquished.

In this branch of his business he was assisted by his son, Mr. Thomas Ross, who, as we before remarked, was the means of at last almost compelling his father's attention to photographic optical requirements, and the management of that department was very naturally confided to the son; in fact, for the last nine or ten years that branch may be said to have been entirely under the control of Mr. Thomas Ross, of course aided in the scientific part by the talents of his father.

The first photographic lens sent out by Mr. Ross was for a lady, Mrs. Massy; it consisted of but two lenses in contact. The next was made for the great promoter of English photography, the Honourable Henry Fox Talbot, and here, at the suggestion of Mr. Thomas Ross, the lenses were separated somewhat, he having noticed the additional "flatness of field" produced by the separation of the components of the "Ramsden's eyepiece." But in this as in a third lens made for Mr. Henry Collier the curvature of field was such as would not be endured now for a moment; and in order to overcome the difficulty that was then regarded as nearly insurmountable, *the damp sensitive paper was pressed between two glasses ground to the requisite curvature.*

Of course photographers know well enough that this defect no longer exists, thanks to Professor Petzval, to whose talent we all owe the portrait lens as now generally made—though by the way, many do not know this fact, the learned professor's name being more often solely connected in imagination with the orthoscopic lens. It was from seeing one of Professor Petzval's portrait lenses, made by M. Voigtlander (the father of the present one), that Mr. Ross went to work in the same direction—not by any servile copying, but by examining the principles upon which it was formed, and bringing his practical knowledge to bear upon it. The first landscape camera and lens made by Mr. Ross is now in the possession of the Rev. J. B. Reade, and his first portrait combination in that of Mr. Fox Talbot, for whom he also constructed a lens for enlarging from negatives, calculated expressly to increase to the extent of four diameters.

The operation, though not well adapted for paper, was however found to answer with daguerreotype.

At the Great Exhibition of 1851 he received for his photographic camera and double combination lens the Council Medal, and also for his labours in assisting the jurors an Assistant Juror's Medal.

In Mr. Ross's decease men of science have sustained a great loss; and photographers, though they will feel it less than others in consequence of his son filling the gap in their behalf, have been severed from one intimately connected with the rise and progress of their engrossing pursuit.

ON THE PARAFFINE-PAPER PROCESS.

By R. L. Maddox, M.D.

If, on perusal, you should find the following remarks of any importance as a continuation to my previous communications on the use of paraffine waxed-paper, may I solicit the favour of their appearing in your Journal. The interest you have shown on the subject, and the attention you think it to merit, have induced me to continue my experiments, and I trust not without some progress.

In the previous formulæ, bees'-wax had been used; but Mr. Jennings, chemist, Southampton, having handed me some *Japan vegetable-wax*, which is said to vary considerably in chemical constitution from the former, though possessing closely allied physical properties, I determined on giving it a trial in conjunction with paraffine oil, anticipating an advantage in the reduction of the silver salts by its use.

Some ordinary paraffine oil was filtered through well-dried animal charcoal; to each ounce twenty grains of the vegetable-wax in shreds was added, aiding the solution by setting the bottle in hot water; also five grains crushed iodide, and one grain bromide of ammonium—no free iodine being used. Papers already albumenised by your formula were soaked for twenty minutes in the filtered solution, dried and sensitised by the formula originally given, which, as an error occurred in the quantity of nitrate of silver, I here repeat corrected.

Dissolve forty grains of nitrate of silver in two drachms of distilled water, add one grain of bromide of potassium, shake well, then add gradually ten drachms distilled water, four drachms Beaufoy's acetic acid, and four grains citric acid. Filter for use. The papers were floated on this until they rested quite flat and appeared nearly uniform in colour, then treated similarly to the former papers.

The first negatives were sent for your inspection. I found the papers thus prepared possessed of much greater sensibility to light as compared with those prepared with bees'-wax: dry, they afforded negatives on three seconds' exposure to sunlight with a double combination lens when treated by the quick method of development, though by the slow method they gave no image; but thirty seconds' exposure gave dense negatives with the gallic acid developer.

A piece of paper thus prepared was placed over a negative which had been taken by four seconds' exposure in shade, with Mr. Jennings's negative collodion (which, by the way, I mention as excellent for the dry process, being exceedingly rapid, and giving good density), and gave, on instantaneous exposure to moderate light, a positive by development on immersion in solution of aceto-sulphate of iron. This experiment was repeated many times, varying the exposure and strength of the solution: some essays gave excellently toned pictures, but often before I could remove them they became dingy and discoloured. This led to the use of a double salt of sulphate of iron and magnesia as a developer, with the addition of citric acid, but it only produced red pictures, which *were not stable* in the hyposulphite solution, turning purple all over after the use of honey, though in the developer the whites were well preserved. I should however observe that it was placed in the same hyposulphite bath as those negatives developed with gallic or pyrogallic acids, hence the tint, I suspect.

When carrying out with the camera some comparative experiments on the sensitiveness of papers prepared with bees' wax, and with Japan vegetable-wax in paraffine oil, on trying to develope one of the pictures by pyrogallic solution, so tardy was the development that I concluded that the slide must have been forgotten to be drawn up, especially as I was temporarily surprised by a young cow rushing towards me with somewhat of wilfulness; so on not seeing any vestige of a picture after the usual time, I washed off the pyrogallic solution, pulled the paper several times through water, and set it aside in blotting-paper for future use. On removing it next day I was surprised to find the picture developed and very fairly out, the paper being perfectly dry. To try and continue this development it was wetted, the blotting-paper damped, and again set aside—the density increased but little; afterwards it was soaked in honey and water, as you suggested, but it scarcely altered. It had been exposed thirty seconds in sunlight. Another negative was taken on similar paper, exposure the same, developed by the pyrogallic solution until fairly visible, then washed in water and in honey and water, and set aside like the previous one, as also one developed by the ferro-sulphate of magnesia. They darkened only in a trifling degree. After five days they were each put in hypo solution, and I now forward these with others.

Continuing the experiments with Japan vegetable-wax, I tried the effect of lamplight to print by. Prepared paper was placed under the previously-named negative, and exposed for twenty minutes near a moderator lamp: no image visible. It was left all night in previously used gallic acid solution, and you will find it amongst the rest of fair intensity. Indeed, to prepare many of the papers by candle-light, I fear I have to attribute a considerable number of apparently overdone pictures, though generally the light was protected by yellow paper.

The question is still open as to the best solvent for the Japan vegetable-wax, which by Sthaner is said to differ considerably from bees'-wax—"double the quantity of oxygen and palmitic acid combined with the oxide of glycocyle." I have papers prepared with it in other solvents combined with paraffine oil, but hitherto have not found the sensitiveness equal to those prepared by the plan given above; nor have I found free iodine of much use in the solution, nor sensitising both sides.

It appears that the papers, when compared with bees'-wax prepared papers, are more readily impressed by light both in time and quality; and I believe that vegetable-wax greatly assists in carrying on the molecular change first determined by the action of light, though how much may be due to the paraffine oil I cannot say; for from former experiments on silver solutions with paraffine oil, connected with the reduction of metallic silver, I was induced to continue its use in combination with some hydro-carbon in the paper process. It seems worth further trial. I have not yet used

the papers damp, but purpose doing so—also after treatment with honey or some deliquescent salts. The papers unfortunately thus prepared are very stiff and parchment like, especially when albumenised, and require close pressing to the glass of slide.

Trusting your superior knowledge in matters of photography may suggest some useful modification, I leave the subject in your hands for such remarks as you may think valuable or necessary. In conclusion, allow me to thank you for the assistance you have already rendered by calling attention to the subject, with the addition of very useful hints in the pages of The Photographic Journal.

September 19, 1859.

[With regard to the use of honey and water for the purpose of continuing the slow development which appeared in the manner described by the author of the preceding paper, it does not appear from his account of the operation that he added any free *nitrate of silver* thereto; that we consider absolutely requisite, in order to obtain an adequate effect—though a very small quantity should be sufficient — probably a drop or two of a twenty or thirty grain solution.—Ed.]

WOODWARD'S SOLAR CAMERA.

We are always ready to afford every opportunity of expressing their sentiments to those who differ from us in opinion, and are not over particular about allowing personalities directed solely against ourself to appear — consequently we readily give admission to the following :—

WOODWARD'S SOLAR CAMERA.

To the Editor.

Sir,—Having read your long and disparaging account of the above-named instrument, wherein you give your own ideas and plans how something better may be constructed, allow me to say some little on the same subject.

There are numbers in this country who have made contrivances to enlarge photographs. Six or seven years back I made an instrument by which I could considerably increase the size of a photograph, and from all I have read or seen, it is the nearest approach to Mr. Woodward's solar camera. This instrument I sold to an artist in this town, who has used it ever since, until he saw the American camera, which he pronounced perfection, and now uses no other.

The arrangements you describe I have tried long since (?), excepting with an orthoscopic lens: those who may be induced to try that, with any other of your arrangements, will (like me) experience expense, loss of time, and certain disappointment.

You seem disposed to write it down simply because Mr. Woodward has patented it. You cannot have the slightest knowledge of the scientific construction, or wherein it outsteps all other contrivances.

This instrument took Mr. Woodward, not days or weeks, but years to perfect it, as it now is given to us. This useful and beautiful instrument well deserves to be protected by a patent. It certainly met with similar opposition in America; many claimed to be the inventor, but, like me, they knew nothing of its construction or worth. The result is, in America every respectable artist has Woodward's solar camera. So it will be in this country ere long. I can give you a host of names that will certify to its usefulness and perfection. Even young as it is here, many who were hostile now possess it.

You say you saw Mr. Kilburn's instrument, and the pictures taken by it, which you pronounce inferior to those by Mr. Wenham. All this is possible. We all consider Mr. Kilburn a very clever artist, and would expect something good from him. An allowance must be made—Mr. Kilburn has but just received his camera, and, from his other business, he may not have had time to perfect himself in the working of it. It will be seen yet that he can produce good and satisfactory pictures. I know what I can do myself, and I am confident he can and will do the same. I am able to produce life-size pictures, with a quarter-plate portrait lens in connection with the solar camera, by sun-light, in two minutes, such as require no artist to retouch. I will increase in length a straight line on the edge of a half-plate picture to twelve or more feet, free from the slightest distortion. I cannot believe that any of the plans you have given on Mr. Wenham's method can come near this.

I challenge all the photographic world to produce a picture that can bear the slightest comparison to one I can produce by Woodward's solar camera.—I am, sir, yours respectfully, JOHN ATKINSON,

Liverpool.

With regard to our correspondent's observations relative to Mr. Kilburn, we have only to assert that the latter is quite able to use *effectually* either the camera in question or any other photographic instrument.

As to whether a portrait requires touching by an artist or not before a purchaser would be content with it — is it not a matter of opinion?

Our correspondent seems to ignore the fact that we take exception to Mr. Woodward's camera because it is *identical* with Mr. Wenham's method, and consequently *not new*. If the one can produce a perfect picture, why so must the other.

We of course pass by without remark the charge of our alleged want of knowledge of the principle of Mr. Woodward's camera; but take leave to remind Mr. Atkinson that our comments upon the subject were elicited by his own and Mr. Woodward's previous letters. We had purposely avoided going into the question from a fear lest we should be called on to condemn—a fear arising from what we had read of the construction of the camera in the pages of some of our contemporaries; but as the subject was brought prominently under our notice, we could not do otherwise than we have done. So long as we have the honour of conducting this or any other periodical, we mean to express our honest convictions without favour or affection. We will not go out of our way to express an unfavourable opinion; but when invited or otherwise called upon to express one, it must be an honest one.

We now append the following on Mr. Atkinson's side of the argument.

A COLOSSAL PHOTOGRAPH.

To the Editor.

Sir,—My first trial for a photograph of large dimensions has been successful.

I have printed by the developing process, on Saturday, September 10th, a full length and "sharp" image (portrait) on an entire piece of calico, of eight-and-a-half by five-and-a-half feet. I was obliged to stop the printing three times, as the sky was cloudy and the sun not strong, but finished the printing in about ten minutes.

I have printed about forty in the last fortnight, all on large-sized smooth Whatman's paper; they are nearly all successful, and are now exhibited in my new gallery for life-size pictures.—I am, yours, &c.

Havelock Buildings, Bold Street, P. C. STORTZ.
Liverpool, September 19*th*, 1859.

We have yet more to add — but enough for the present.

British Association.

Aberdeen Meeting, September, 1859.

(From our Special Reporter.)

As this Journal is essentially a photographic organ, it is not our province to notice the papers on general Science brought before the various Sections. The scope of our art lay within the proceedings of Section A (Mathematical and Physical Science), and Section B (Chemical Science).

One or two circumstances, however, gave special interest to the Aberdeen Meeting, to which we may devote a small space before passing on to the strictly photographic part of the subject.

In the first place, the presidency of H.R.H. the Prince Consort gave an *eclât* to that meeting that in a pecuniary sense made it the most successful one in the history of the British Association, the members and associates numbering nearly 2600 (a number unprecedented in its now long career), embracing the high-born in station and the distinguished in Science, Art, and Commerce. The Continent of Europe was ably represented in its men of genius, and America sent some of her most distinguished *savans*. Even Syria had its representative in Mr. Antonius Ameuney, who delighted Section E with a paper *On the Arab Speaking Population of the World*—no less by the broad and enlightened views which he enunciated than by his thorough knowledge of our language, which enabled him to lay his statements before his auditory in a perfectly clear manner, while his finished style and ready wit gave point to his address.

Another source of more local interest which marked the late meeting was the inauguration of the very elegant Music Hall, in which took place the *conversazioni* and general lectures. Among the many fine buildings of which the "Granite City" can boast the new County Buildings, to which is attached the Music Hall, will take high rank—not only for the chasteness of the architectural style, exterior and interior, but for their perfect adaptability to the special purposes for which the whole have been designed. The acoustic properties of the great hall reflect the highest credit on the architect, and its appearance upon the late occasion, when filled with the rank and beauty of the surrounding country, was light, elegant, and graceful. Nor has the important point of ventilation been overlooked, as was proved by the moderate temperature of the building when filled to overflowing during the

recent meetings. The possession of this noble Hall and the splendid suite of rooms attached, gave to the local authorities and officers of the Association "ample room and verge enough" for the purposes indicated above, which the British Association we believe nowhere else enjoyed to the same extent, except in St. George's Hall, Liverpool. The meetings of the various Sections took place in the Marischal College, which was temporarily vacated for the time being. The accommodation thus afforded was excellent.

On the general sectional proceedings we shall make no comment, except on the mode of preparing the business of the meeting, which, as at present practised, we think objectionable.

The present method of arranging the proceedings day by day during the meeting necessitates haste and a want of method in the conduct of the business, which result in important papers being only half read and a precipitancy in the closing of discussions which is detrimental to advancement in Science, and not courteous to the gentlemen whose papers have cost much thought, labour, and anxiety. How often, as "iron sharpeneth iron," does the contact of thought and the abrasion of mind evolve important truths, give more point and consistency to the paper read, and *advance* in a true sense the knowledge of the world! As twelve months elapse between this meeting and its successor, there is time for those gentlemen having experiments in progress, and others to whose mind subjects of interest present themselves ere the next meeting at Oxford, to prepare carefully—and not hurriedly as is too much the system at present—to bring certain definite questions before the Association in its various departments. The system of receiving papers up to almost the last hour of the Association's meeting encourages procrastination, which is not only the thief of the author's time but of the members who take an interest in the subjects brought before the sections. We would suggest, therefore, in order to economise the short time to which the annual meetings of the British Association is confined, that a precise period *before* each yearly meeting be fixed for receiving papers (not the *names* of papers), and that none be received after such date. That all papers should be *complete*, both in the text and the diagrams, to prevent the evil (of which we have too much reason to complain in connexion with the late meeting) of gentlemen of even high scientific position apologising for unfinished papers and not fully digested thought upon their subjects. Our plan would enable the proper officials to have printed and ready for circulation among the members and associates, on the first day of meeting, the *Journal of Sectional Proceedings*, containing the business of the *whole week* methodically and carefully arranged for each day, thus giving some time for the preparation and discussion of every subject brought forward.

We confess we have an opinion that a properly conducted discussion frequently brings out more important facts relative to a given subject than is contained in the paper which provokes it. Some better system for the conduct of the discussions than at present exists should be adopted, in order to prevent the time of the sections being frittered away, as happened in many cases at the Aberdeen meeting. We would only allude to one instance which occurred on the last day of the sectional meetings. In section A no fewer than *thirty* papers were put down to be read on that day. The opinion of a certain learned professor was challenged on an important point, and the gentleman (to whose opinion all reflective minds pay deference) proposed to occupy the section only a few minutes; but, notwithstanding his own promise and the known amount of business for the day, the worthy professor spoke for more than an hour on his pet subject. Similar instances of useless loquacity (in which speakers repeated themselves frequently) might be adduced. Enough has been said, however, to illustrate our opinion that a fixed period should be given to each speaker, who ought to come to the section prepared (owing to the method we have proposed of giving due notice of the subjects to be brought forward each day) to condense his address so as to keep within the specified time for all who take part in the discussions.

It would perhaps be advantageous that the authorities of the British Association should discourage the scientific discursiveness of its members. Pope says, "one science only can one genius fit." There may be mathematical minds of sufficient magnitude to prepare subjects in more than one department of general knowledge, but the instances are few. One carefully-prepared and well-digested paper on *the* subject of science or art to which the life and solicitude of the writer has been specially devoted, would be more likely to add to our stock of knowledge, and *advance* the cause of science, than numerous crudely-prepared papers on various subjects, as in the late meeting were eliminated from the mental *manufactories* of some learned gentlemen, foreign and English.

Lastly we would suggest that the Council of the British Association should discourage at its meetings the growing evil of allowing any gentleman — be he English or foreign — bringing indiscriminately and prominently forward *patented* articles of little value, with the sole view of *advertising*, with the apparent sanction of the Association, perhaps worthless inventions. If such patented inventions are really valuable there are legitimate modes of advertising them other than in the section rooms of a learned society. Certainly great caution at least ought to be exercised in their admission at the Association meetings.

To turn to other and more pleasant subjects connected with the Aberdeen Meeting, we may say that the opening address of the Royal President took the audience by surprise; and if he omitted to review, as is usually the case in such addresses, the advance of Science during the past year—bringing prominently before the members the more salient points of progress in the various departments of human knowledge during that period—yet there was so much force and truth in the address, that the vast assembly was astonished and delighted at the wide range of his Royal Highness's knowledge, and that he could in our language place the conceptions of his mind so faultlessly before his audience. The Royal Consort of our beloved and gracious Sovereign has raised himself by his able address on this occasion in the estimation of the thoughtful portion of her Majesty's subjects.

Supplementary to the intellectual treat provided by the Association in the Sections and in the Music Hall, local bodies had opened at the same time, for the delectation and amusement of the visitors to the city and of the general public, photographic, archæological, and horticultural exhibitions, an exhibition of historical portraits and objects of antiquity, and collections illustrating the geology, &c., of the North of Scotland—to all of which the members of the British Association were admitted on showing their tickets. The admirable manner in which these various collections and exhibitions were organised by the gentlemen to whom the arrangements were intrusted, exhibited great taste, judgment, and intelligence, which reflected much honour on their native city. In the excellent Photographic Exhibition we took of course especial interest, and elsewhere will be found an estimate of the principal pictures.

At both the *conversazioni* many objects of high interest were arranged around the great hall, and the music of the organ (though the instrument was unfinished) lent its influence to enhance the pleasure of the crowded assemblies. The appearance of the hall filled by company was brilliant in the extreme. If the assemblage present on each of those occasions — mainly drawn from the northern counties as no doubt it would be (Aberdeenshire of course being best represented) — can be taken as a type of the womanly beauty and manly proportion and strength of the North of Scotland, it would compare most favourably with that of any other city or town in her Majesty's dominions. The idea of holding these *soirées* is a happy one, for at them grave men of science can unbend and fraternise with the less cultivated portion of the public. On the evenings of these assemblies the interior of the hall was a study for an artist. The varied colours of the ladies' costumes — the stream of black-coated and white-neckclothed gentlemen almost vainly endeavouring to effect locomotion among the wilderness of crinoline — here and there a Highland costume or foreign dress giving variety to our English attire—the delightful babel of tongues, foreign and domestic (among which could be detected the peculiar accents of Belfast, Kilkenny, Cork, and Dublin, the more musical though not less varied sounds from southern counties, the broken English of some French, German, or Russian *savant*, mixed up faintly with the predominating utterances of our Scottish friends)—all conduced to render the scene at once animated and pleasant to both eye and ear.

We must not omit to add that Messrs. Smith, Beck, and Beck, of London, exhibited at the *soirées* some of their educational, one of their students', and one of their most complete achromatic microscopes, combining the highest magnifying power with the greatest delicacy of mechanical arrangement. The light used with them was their improved belmontine lamp. Whilst these instruments received a very large share of attention, those which attracted the greatest notice were their achromatic stereoscopes, in which were exhibited Mr. Warren de la Rue's photographic views of the Sun, Moon, and Saturn. In the first advantage having been taken (for the production of the stereoscopic effect) of the rotation on the sun's axis, and the consequent change in the position of the spots. Whilst in the last the same effect was produced by combining photographs from two lithographic views, drawn from micrometrical measurement, taken at an interval of three years, the result being obtained from the difference in the plane of the orbit as

viewed from the earth. The stereoscopic effect produced by all of them was most satisfactory, and showed the advantage of this mode of examining the form of the celestial bodies.

The admirable arrangements made by the local officers of the Association, aided by the hearty co-operation of the Lord Provost, tended greatly to the success of the meeting at Aberdeen. To Mr. White, one of the local secretaries, we are indebted for much assistance, and we take this opportunity of acknowledging his kind aid.

We shall now proceed to give those papers connected with the art of photography which we were enabled to procure or report, with some portions of the discussions which followed the reading of them.

The following is extracted from the Report of the Kew Committee:—

"Since the last Meeting of the Association, the unfortunate death of Mr. Welsh has retarded the experiments with the Photoheliograph, but from time to time they have been gone on with, at first by Mr. Chambers, who obtained some very fair results, and latterly by Mr. Beckley, as his other duties have permitted; and in order that they might be prosecuted more continuously, the Committee have fitted up a photographic room in close contiguity to the instrument. This addition to the photographic establishment has been attended with the most promising results; and the Committee have satisfaction in reporting that the difficulties which have hitherto presented themselves in the way of a daily photographic record of the sun appear to be almost entirely surmounted. Since the erection of the photographic room, Mr. Beckley has been enabled to make a series of experiments, and has turned his attention to the exact determination of the chemical focus of the Photoheliograph, which there was reason to suspect did not correspond precisely with the visual focus; for although the chromatic aberrations of the object-glass had been specially corrected in order to obtain that result, the secondary-glass, which magnified the image, was not so corrected. It has been found, after repeated trials, that the best photographic definition is obtained when the sensitised plate is situated from 1-10th to 1-8th of an inch beyond the visual focus in the case of a 4-inch picture; and that when this adjustment is made, beautiful pictures are obtained of the sun, four inches in diameter, which still bear magnifying with a lens of low power, and show considerable detail on the sun's surfaces besides the spots, which are well defined. Mr. De la Rue, by combining two pictures obtained by the Photoheliograph at an interval of three days, has produced a stereoscopic image of our luminary, which presents to the mind the idea of sphericity. Under Mr. De la Rue's direction, Mr. Beckley is making special experiments, having for their object the determination of the kind of sensitive surface best suited for obtaining perfect pictures; for it has been found that the plates are more liable to stains of various kinds, known to photographers, under the circumstance of exposure to intense sun-light, than they would be if employed in taking ordinary pictures in the camera. Now that the photographic apparatus has been brought to a workable state, Mr. De la Rue and Mr. Carrington, joint Secretaries of the Astronomical Society, propose to devote their attention to the best means of registering and reducing the results obtained by the instrument, provided the funds which may be necessary are placed at their disposal. The difficulties which have stood in the way of bringing the Photoheliograph into an efficient state of work were such as it required no ordinary degree of perseverance to surmount; and the Committee have therefore the greater satisfaction in reporting that these have been overcome, in so far as to render the Photoheliograph a valuable recording instrument:—the minor improvements still contemplated have for their object the production of pictures as free as possible from the spots and blemishes to which all photographs are liable, and sun-pictures in particular."

Friday, September 16th.

SECTION A.

Mr. A. Claudet, F.R.S., read short papers *On the Stereoscopic Angle; On the Focus of Object Glasses; On the Stereomonoscope;* and *On a Changing Diaphragm for Double Achromatic Combinations.*

Our reporter was unfortunately engaged in another section when these papers were read. Mr. Claudet not having quite completed his MS. in time for the meeting, was unable to furnish us with abstracts, but has promised them in time for our next publication.

Saturday, September 17th.

SECTION A.

ON A NEW PHOTOGRAPHIC LENS.

By Thomas Sutton.

Up to the present time no lens which has been used by photographers for the purpose of copying architectural subjects has been capable of rendering correctly the image of a straight line in the margin of the picture. When the common form of the photographic view lens is used, which consists of an achromatic meniscus, placed with its concave side towards the object, and with a stop at some distance in front, the marginal lines of the picture which should be straight are rendered concave towards the centre of the picture; and when the Petzval view lens is used, which consists of an achromatic meniscus, placed with its convex side to the view, and a much smaller achromatic concave lens placed at a certain distance behind it, and having a stop in contact with it, the marginal lines of the picture which should be straight are rendered convex towards the centre of the picture. In fact no photograph of an architectural subject taken with the lenses in common use will bear the test of a straight edge applied to the marginal lines, which are always curved either inwards or outwards.

In the present paper I will describe a combination which I have invented, by which the above effects of distortion are totally obviated, and which gives an image that is mathematically perfect. I may add that this lens was recently tested by a Committee of the Photographic Society of Scotland against the best forms of the common lenses, made by the most celebrated makers, Voigtlander, Ross, Goddard, &c., and it was pronounced to be the only lens which gave an undistorted image — at the same time that it satisfied all the conditions of a good lens.

The conditions for obtaining an image free from distortion are these:—

1st. The axis of every pencil must emerge from the combination in a direction parallel to that of incidence.

2nd. The axis of every pencil must pass through a certain fixed point.

3rd. The image of every luminous point of the object must be formed at the point where the axis of the pencil meets the focussing screen.

These conditions are rigorously fulfilled by the lens which I have invented and will now describe.

The combination is a symmetrical triplet, consisting of two equal achromatic plano-convex lenses, one at each end of a tube, placed with its convex side outwards — and a small double concave lens of equal radii placed exactly midway between them. In contact with the double concave lens a small stop is placed.

It is evident that in this combination a small oblique pencil is incident excentrically upon the front convex lens — that its axis after suffering deviation passes centrically through the concave lens without suffering further deviation — and that it is then incident excentrically upon the posterior convex lens, from which it emerges in a direction parallel to that of incidence.

The above is true of every oblique pencil, and their axes all pass through a common point, which is the centre of the symmetrical combination — and which point I will call C.

The 1st and 2nd conditions are therefore fulfilled.

The proof that the 3rd condition is also fulfilled is as follows:—

The focus of an oblique pencil is in every optical instrument a disc of light, and not an exact point. The size of this disc is reduced by using a small stop. When it is sufficiently reduced by using a sufficiently small stop the focus upon the screen is said to be good. In that state the ray which passes through C (and which I have called the axis of the pencil) is one of the rays which compose the small disc or good focus, because C is at the centre of the stop. The focus is therefore at the point where the axis of the pencil meets the focussing screen; and therefore the 3rd condition is fulfilled.

It is necessary in every kind of photographic view-lens to use a small stop, because the objects of a view are at different distances from the lens, and a good focus cannot be obtained in any other way. The use of a small stop is not therefore confined to my triplet; and when the image is rendered sharp and distinct by the use of a small stop, it is also totally free from distortion.

By a fortunate circumstance the triplet gives an image which is equally illuminated in every part, because the area or base of the oblique excentrical pencil upon the front lens is greater than that of the direct central pencil, and in this way the loss of light from obliquity is counteracted

Spherical aberration in the direct central pencil is totally corrected, because the negative aberration of the concave lens counteracts the positive aberration of the convex lenses. There is consequently brilliant definition in the centre. At the same time the marginal definition is as good and the field as flat as that of any lens now in use.

In order to get good marginal definition and the proper flatness of field, the distance between the convex lenses should be about one-sixth of their focal length, and the focus of the concave lens should bear to that of the convex lenses the ratio of about 13 : 8.

SECTION B.

ABSTRACT OF REPORT ON THE PRESENT STATE OF OUR KNOWLEDGE REGARDING THE PHOTOGRAPHIC IMAGE.

By Professor MASKELYNE, J. D. LLEWELLYN, F.R.S., T. F. HARDWICH, and E. HADOW.

IN this report the authors confine themselves to the results obtained with salts of silver; and the question first considered is the chemical condition in which the silver remains when light has completed the decomposition of the chloride as far as it can go. Is the result a sub-chloride of silver, or one where escaping, the chlorine and silver are completely dissevered, the gaseous element and the metal remaining mixed with, or rather incrusting particles of unaltered chloride?

The paper then proceeds to detail certain experiments with reference to the determination of the question, bearing in mind that in the photographic processes which require chloride of silver that substance is not used by itself, but always in conjunction with nitrate of silver and also with organic substances, among which the paper and the size upon it are prominent. The authors considered that they were justified in drawing the following conclusions:—

1. That the action of light on chloride of silver, is to reduce it in so far as it is able to penetrate its substance to the state of a sub-chloride.

2. That in the presence of nitrate of silver this deposit of sub-chloride is necessarily more plentiful, but that in both cases, moisture being present, some part of the liberated chlorine passes into an oxide, which in the latter case prevents a portion of the chlorine set free from conducing to the formation of fresh sub-chloride.

From this point they proceed to the discussion of the photographic image in more complex, but for the photographist more available, forms. And in doing so, they point out that the image varies in its character in different stages of the photographic process. The first result obtained by the light, even if it be the same in all stages of the insolation, is not the result which is in many cases left after the fixing solution has performed its work, while this is again frequently succeeded by another variety of image by the employment of the methods called toning.

The results at which they conceived that photographic chemistry may be said to have now arrived, in respect to the direct processes involving the use of silver salts, may be thus stated:—

The materials employed perform various functions—

1st. One of these is that of supporting the picture as a mechanical material or basis for holding the chemical bodies. Of the substances so employed, the tissue of the paper is one. Pyroxyline is spread on glass to afford another; the latter appears to be inert, the former, on the other hand, seems to aid in producing the chemical results.

2nd. The silver salts employed, whereof the chloride (for which other salts may be substituted, each with a specific effect), appears to act by imparting *sensitiveness;* the nitrate, on the other hand, is present in excess to keep up a constant succession of sensitive material, and so to give *vigour* and *intensity* to the image.

3rd. Gelatine as a size, or albumen as a glaze, and various other substitutes for these, but little linked together by any chemical analogy amongst them, co-operate by conferring *rich tints* and deep tones, while they impart to the image formed on them an immunity from the destroying action of the fixing process, and form a mechanical service more or less impenetrable, which prevents the other sensitive compounds from sinking into the paper.

With reference to photographs produced by development, the several causes which determine the deposit of the images in their several states appear to be these:—

1st. *Materials forming the sensitive film.*—Pyroxyline in chemical purity has no tendency to form the darker image. Albumen and the heterogenous substances (including decomposed collodions), which we have had to yoke in the same class with it have this tendency. In general the tendency to produce the darker image is found to be in something like an inverse ratio, *cæteris paribus*, with the sensitiveness. The use of bromide of silver with iodide imparts to a collodion film a tendency to deposit the metallic image, at the same time that the sensitiveness is much impaired, and a very powerful reducing agent is needed to develop it. With albumen the influence is not felt, for with albumen, bromide of silver is held to increase the opacity of the image

2nd. *The nature of the developing agent.*—The substances used to develop the latent image, besides the free nitrate of silver invariably necessary, embraces also without exception one ingredient the character and the purpose of which is to reduce the salts of silver.

3rd. *The character of the light* has also a remarkable influence in inducing a grey or a dark character on the developed image. If the picture has been produced by an intense light, as by a lens of large aperture, or as in the case of an exterior as contrasted with an interior view of a building, or as on a dull misty day in contrast with a bright and sunny one, it will be found that, *cæteris paribus*, the tendency of the shorter action of the light is to allow the reduction of the silver in the metallic form. On the other hand, more intense light has given to the molecules of the sensitive film a controlling energy, which they exercise on the deposit, and which appears analogous to that of the light in the direct process in its modifying the reduction, and giving it the form of a production of an argentous compound. As though the iodine compound became in a certain sense phosphorescent to the chemical rays of the light, and operated upon the mixed silver salt and the reducing agent, as they float over it, in the manner that the direct light might be supposed to do.

The PRESIDENT (Dr. Lyon Playfair) said—A report upon the subject of the chemical character of the photographic image has long been desired; and although we are unable, on account of the length of the report, to do full justice to it on this occasion, no doubt, when we have an opportunity of reading it at leisure, we shall find that many useful deductions have been made, and apparently with great caution. Unfortunately our ignorance of what the true chemical character of the photographic image is, is at present very great. As it was, one or two little points which have occurred to many chemists made it desirable to go into them more particularly; and there is one experiment which I may mention, as I happen to know it, and as it is a very striking one, that would give some indication of the nature of the photographic image. If you take any calotype, and dip it into a solution of bichloride of mercury, it becomes perfectly white, and no vestige of the image remains; but afterwards, if it be placed in hydrosulphate of soda, it becomes completely restored. The mode in which the chloride of mercury acts in rendering the image latent, has as yet, as far as I am aware, received no satisfactory development.

ON A PHOTOGRAPH OF FLUORESCENT SUBSTANCES.

By Dr. GLADSTONE.

IT is well known that the rays of light which are effective in producing photographic images are not the most luminous—that they are those which have the most refrangibility, as the violet, or what have been called the lavender rays, and others invisible to the eye, but which are extremely active upon the chemical substances.

It is known also, especially through the researches of Professor Stokes, that many bodies have the power of altering the refrangibility of light—that disulphate of quinine, for instance, is a body which in solution transmits all the visible rays of light; but that there are certain of those invisible rays which are effective in producing photographic images, which by the disulphate of quinine are altered in their refrangibility, and become blue, so that we actually see a peculiar blue upon the surface of the liquid when they come in contact with it. It has occurred to me very frequently, that if we had a photograph thus prepared, we should very probably find that the chemical rays, being altered in their refrangibility, were removed from the field of action, and that they gave no image. Dr. Wilson brought similar ideas before the Photographic Society of Scotland, and they were published; but it appeared to me that no one was actually performing the experiment; so a short time ago I prepared these two pieces of paper. [Dr. Gladstone referred to the two pieces of paper he had used in his experiment, and which he exhibited]. On the first sheet I have written something in a thick solution of mixed ditartrate and disulphate of quinine. On the other paper I have made a little drawing with ink of a branch, and drawn the leaves in chlorophyll. The way in which it was prepared was this:—take tea-leaves which have been exhausted with water till all the colouring matter is removed, steep them in alcohol, and you have a solution of very little colour, but highly fluorescent; and this is the substance which I have employed in drawing the leaves with. I had a photograph taken of these papers: I did not know whether the conditions were right to produce the effect, but I find that there is no mistake whatever as to the effect. When I looked at the image of

these papers in the photographic camera, so as to obtain the focus, I could not see the slightest trace of anything on this paper. I noticed this especially in the second experiment. The image came out perfectly distinct when it was developed. [The photographs were handed round the room]. I have no doubt that more striking results still may be obtained, by using different substances, and using them in different proportions. I can easily imagine, for instance, that we might, instead of producing a varied image from a paper on which nothing is visible, obtain a result the actual reverse of that which is presented to the eye. Thus, there are many papers of a blue or purple colour which give a very great photographic effect; and I can easily imagine that by taking such a paper as that, and writing upon it with disulphate of quinine, putting it on thick, so as to cause the writing to be white, and the paper to be of a deep colour, when the image was developed the paper would come out white, and the writing upon it dark in colour. I have merely brought forward this experiment to show that what theory rendered probable is really the fact.

M. Abbé Moigno then exhibited *Two Photo-Chemical Experiments, by M. Nièpce de St. Victor.* He accompanied the exhibition with an address in French.

The President subsequently detailed the substance of the Abbé Moigno's remarks in English, which we append.

The President said—For those who did not understand the Abbé's remarks, I may repeat what he has said. A solution is made of oxalic acid and salt of uranium. Oxalic acid is placed in the solution, and in the dark nothing happens, but when it is exposed to light, the light coming upon the oxalic acid decomposes the latter, producing carbonic oxide and carbonic acid. By the tube which is used we are able to measure the intensity of light, so that it is a kind of photometer. The other experiment is similar to the first. In this solution there is placed a galvanic coil (connected so as to form a complete circuit). In the dark there is very little deflection of the attached galvanometer, but when exposed to the light there is a great deflection, and by the amount of this deflection it is possible to measure the intensity of the light. The photometer seems to me to be exceedingly ingenious, and likely to produce very useful results.

Dr. Gladstone: I have been very much interested in the matters which have been brought forward. You are all aware that Professor Bunsen and Dr. Roscoe have brought forward and used a photometer of great delicacy and beauty. Unfortunately, however, it is so complicated, that I fear very few except those manipulators themselves will be able to make use of that instrument. We want a good and practical photometer, and this may be the one that is required. I remember that at the last meeting of the British Association, at Leeds, a young man, Mr. Fowler, brought forward a paper which struck me as being a very excellent one for this subject. He had employed a mixture containing oxalate of mercury, if I remember rightly, and had obtained results of very great interest, showing the influence of time upon the action of the sun on these substances. I hope he has been going on with his experiments and that we soon shall hear more of his results.

Abbé Moigno then made an interesting communication in French in regard to *a Collection of Photographs in Charcoal and Metallic Powder, and Photographic Enamels,* which he exhibited. We again avail ourselves of Dr. Lyon Playfair's explanation.

[A number of beautiful photographs in charcoal, principally executed by M. Lafon de Camarnac, the inventor, as well as several fine enamels on the new principle explained by M. l'Abbé, were handed round and examined by the Section. Some of the photographs were coloured with dragon's blood].

The President said—The first process which has been brought before us by M. l'Abbé Moigno is a very important one, and has been apparently brought to great perfection in France. It is the method of having charcoal photographs instead of the ordinary silver ones. The process consists in using—first a mixture of gelatine and bichromate of potash; the parts of the gelatine on which the light falls become insoluble in water, and more or less soluble according as the light falls with more or less intensity. The photographs are then exposed to the action of the vapour of water, and the portions which have not been acted upon by light become capable of removal, and then charcoal powder is dusted over the photograph thus prepared, and you see it produces calotypes of great beauty, and of a substance which is quite indestructible, either as regards the chemical action of oxygen or that of light. The other photographs, such as those of different colours, are produced in the same way; only instead of charcoal powder, coloured materials are used. The second part of the Abbé's communication was still more curious; and that was the production of enamel by a similar photographic process. In the same way the material used was a mixture of gelatine and bichromate of potash, and then the pulverised oxide in a fine state of powder is sifted over it. Then it is melted in the ordinary enamel furnace, and it becomes a true enamel. The last part of his communication was to the effect, that various chemical agents, which produce different colours, such as Prussian blue, cobalt, iron, and so on, may be employed to obtain colours of different degrees of brightness; in fact such as we have seen presented lately by Mr. Mercer to the Chemical Society.

The President having invited discussion on the various photographic papers of Dr. Gladstone and the Abbé Moigno,

Dr. George Wilson, Professor of Technology, Edinburgh, said:—I ask the attention of the Section to the very distinct communication which was first laid before us, on the possibility of producing a positive effect from a seemingly invisible line drawn in sulphate of quinine. Dr. Gladstone referred to a communication which I made to the Photographic Society of Edinburgh some years ago, but I may say the credit of that belongs to him, for I went no farther than perhaps most would have done. When light falls on a fluorescent surface, and then is reflected from it, Mr. Stokes explained then the effect of the fluorescent body is to convert a ray of a certain refrangibility into one of a lower refrangibility. If we acknowledge the fundamental principle of the co-relation of forces, then we cannot expect to change an invisible chemical ray into a ray of light, and retain the same chemical power. It now appears from Dr. Gladstone's observations that a fluorescent surface, such as one of quinine, appearing to the eye equally white with a surface of paper, reflects a ray of considerably less chemical power; and certainly the fact is one of very great interest, and I presume may be generalised to all fluorescent substances.

Now, there are several points of interest connected with this beautiful observation. It would be very curious to know if it be possible to convert a ray originally taken from beyond the violet, and having a very high actinic power, into a ray deprived of chemical action altogether, as so far as Dr. Gladstone's observations have gone we have not reached the decision of that question one way or another. In regard to a perfect photograph, plainly two surfaces of paper, to the eye seemingly equally white and equally suitable for being made the recipients of a positive photograph, may in reality differ very much in their fitness for that purpose, as the one is more highly fluorescent than the other. Let me point out in what way this is an object of interest. We have copies now taken largely of coloured pictures of oil paintings or water colours, by the camera obscura, as photographs. We are in the habit of speaking of certain effects as admitting of being obtained from certain colours; and we lay down a rule in regard to that. But suppose, for example, we had an oil painting where much red occurred, and that the red used by the oil painter was vermilion; that a copy is made in water colour, and that the red used there is carmine, and to make the case very striking, that a third copy is made where the colour used is the red bichromate of lead, or the iodide of mercury. You may have these copies with the red equally pleasing to the eye. We should, according to the canons at present laid down as to the copying of colours in the camera obscura, expect to find all the reds of the three pictures come out, *cæteris paribus*, equally good or equally bad; but when we observe this result of Dr. Gladstone's, and remember that carmine is a decidedly fluorescent body, whilst vermilion and the iodine of mercury are not, it is plain we should have a difference in the results of the photograph, altogether apart from the effect of colour. The colours may be indistinguishable by the eye: the eye cannot detect invisible fluorescence, but the moment the photograph of the copy is taken it will betray itself. I cannot help suggesting, especially as we have standing committees reporting to us on the chemistry of photography, that their attention should be particularly directed to this matter. Sooner or later this would lead us to a law regarding it. Let me point out a very curious example which was brought before my notice by a well known active member of the Edinburgh Photographic Society, a clergyman, who has taken many photographs in the Pyrenees. He had occasion to copy a photograph of a sloop. He obtained the device of it on a sheet of paper prepared in the ordinary manner for a positive impression. This he put into a frame of glass and exposed it to light, but owing to the thinness of the paper not quite filling up the case, a plain sheet of paper, merely for the sake of thickness, was put in to make up, and the

whole exposed in the ordinary way to the action of light. By and bye this was removed, the copy being made. He again had occasion to make a similar copy this time of a ship. He arranged matters as before, and as it chanced took the former plain sheet of paper and placed it as before, and copied the second subject in the same way. He had occasion afterwards, I do not know for what reason, to charge this same plain sheet of paper with a silver salt and expose it to light, and was astonished to see come out the image both of a sloop and of a ship. He has given me one of the impressions, where in fact, lying at the back, in a very strange way, the most prominent parts of the picture have made an impression which remained there for days, and became permanent when a silver salt was employed. I hope my suggestions in regard to coloured photographs will not be lost sight of by the photographic committee.

Mr. Taylor: There is one fact in regard to the ordinary silver photographs which I have never seen mentioned, and that is, that unless great care is taken it is exceedingly likely that chlorine may find its way into the operation and produce bad results.

The President remarked that now very generally means are taken of removing any traces of chlorine.

Monday, September 19th.

Section A.

CELESTIAL PHOTOGRAPHY.

By Warren de la Rue, F.R.S.

Professor Bond, of Cambridge, in the United States, was, so far as I know, the first to make a photographic picture of a celestial body. By placing a daguerreotype in the focus of the great refractor of the observatory of Cambridge, of fifteen inches aperture, he obtained a daguerreotype of our satellite. This was, I believe, about the year 1850; as I remember seeing one of these pictures in the Exhibition of 1851, and was so charmed with it that I determined to try and do the like at the first opportunity.

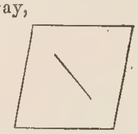
At the latter end of 1852 or the beginning of 1853 (the exact period I cannot now fix), I made some successful positive lunar photographs on a collodion film, by means of an equatorially-mounted reflecting telescope of thirteen inches aperture, and ten feet focal length, cast and polished by myself; and I believe I was the first to use the then newly-discovered collodion in celestial photography. In taking these early photographs I was assisted by my friend Mr. Thornthwaite, who was familiar with the employment of that new medium. At that period I had not applied any mechanical driving motion to the telescope, so that I was constrained to contrive some other means of following the moon's apparent motion. This I accomplished by hand, by means of a sliding frame. The motion of the slide being adjusted to suit the apparent motion of our satellite, the pictorial image of the moon could be seen through the collodion film, and could be rendered immovable as regards the collodion plate, by causing one of the craters to remain always in contact with a broad wire, placed in the focus of a compound microscope, affixed at the back of the little camera-box which held the plate. Although the photographs were taken under the disadvantage referred to, namely, the want of a driving motion, nevertheless the excellent results obtained showed how perfectly the hand may be made to obey the eye.

I could not, however, proceed in taking photographs of the moon in this way alone, but required always the aid of an experienced coadjutor, willing to lose the greater part of his night's rest, and often to be disappointed — failures resulting from the passage of clouds, and numberless impediments sufficient to damp the ardour of the most enthusiastic. For some months Mr. Thornthwaite was so good as to continue his invaluable aid, and several good pictures were obtained by us; but the difficulties we had to contend with were so great, that, after taking a certain number of pictures, it was at last resolved to discontinue my experiments until such time as I had applied a driving motion to my telescope. This was done early in 1857, since which period I have unremittingly followed up the subject whenever my occupation and the state of the atmosphere has permitted me to do so. With what results, the Association will have an opportunity of judging by the examples now on the table. [Mr. de la Rue exhibited several very fine lunar photographs, largely magnified, which were examined and much admired by not a few of those present].

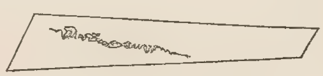
Some time after I had discontinued my experiments in 1853, Mr. Hartnup, of Liverpool, by himself, and aided by Mr. Crookes and other photographers, took some good pictures of the moon, as did also our excellent officer, Professor Phillips. Father Secchi at Rome, Mr. Fry, at Brighton, Mr. Hoggins, near London, have also produced lunar pictures. It is almost needless to say that Professor Bond, of America, continued to follow up his researches in celestial photography with the great refractor; but I may mention how, that before his death he applied his process with promise of a fruitful future, in measuring the distances and angle of position of double stars, and in the determination of their magnitudes; and that of late years this new application appeared to have engaged his attention more than lunar photography.

The mention of photography — one of the last applications of our art — reminds me that the image of such a heavenly body being of the most simple form, it would render what I shall hereafter have to say more easily understood if I were at once to introduce to your notice what happens in applying photography to sidereal astronomy. The optical image of a fixed star, be it remembered, is an optical point, which in consequence of the properties of light is seen in the telescope as a very minute disc surrounded by certain rings, which become fainter and fainter as they enlarge, these rings being always more or less broken up according to the state of the atmosphere; the photographic image, on the other hand, is a mere speck, difficult to find among other specks present in the most perfect collodion film, when viewed with a high magnifying power.

Let us now suppose we have a telescope to be turned upon α Lyræ, which is conveniently situated, from its great altitude on the meridian, for photography, and is moreover sufficiently brilliant to give an instantaneous picture. If the telescope be steadily supported at rest, the star will, in consequence of the earth's rotation, come along the field of the telescope in a line parallel to the earth's equator; and as it produces an instantaneous picture, the image obtained is a line indicating the path of the star, thus, for example. [Mr. De La Rue indicated the form of the image on the black board in this way,



and continued.] We should be led to expect, *à priori*, that the line for the short distance it is made would appear straight; but so far from this being the case, the line is much broken up and disturbed, and consists of an immense number of points, crowded in some places and scattered in others, thus —



This arises from disturbances in our own atmosphere, which cause the optical image to flit before the eye, which nevertheless can make out the proper figure of the image, although it dances before it several times in a second, and the mind is able to select and remember only the states of most perfect definition. The photographic plate, however, remembers and records all the disturbances, and hence presents as a result a number of positions of the point of light, and consequently a less beautiful picture than we see optically.

In the foregoing remarks it was supposed that the telescope was at rest; but now let us suppose that the telescope is mounted on an axis parallel with the earth's axis, and provided with a driving apparatus, capable of carrying the telescope round in the direction of the star's apparent path, so equally, that if viewed by a micrometer eyepiece, the star would remain in contact with one of the wires of the eyepiece. The photographic image of a star obtained by a telescope, under these conditions, after some seconds' exposure, is not one clear disc or point, but a conglomeration of points, extending over a greater or less surface, according as the atmosphere produces a greater or less flickering.

A photographic image of a star, after an exposure of some seconds, is consequently a disc of comparatively large dimensions in comparison with the true image which can be really seen on the plate. It will readily be seen, that as a single point like a fixed star acquires comparatively large dimensions on a sensitised plate exposed for some seconds to its action, so must every optical point in an image of other celestial objects from the same cause occupy a space of greater or less dimensions; hence the photographic image will never be so perfect as the optical image given by the same telescope until we can produce pictures of all objects instantaneously, and we are a long way from this desirable end at present.

Notwithstanding, however, the disadvantages under which the photographer labours, I have obtained pictures of celestial objects, showing details which occupy a space less than two seconds in each dimension—I might, I think, say even one second. Now one second $= \frac{1}{800}$ of an inch on the collodion plate, and a second on the lunar surface at the moon's mean distance, being about one mile. The lunar picture in the focus of my telescope is about $1\frac{1}{10}$ inch diameter, but this varies of course with the distance of our satellite from the earth. It will be conceded much valuable work has already been done, and that if the photographs are taken for a number of years, silenological disturbances will not escape detection if they take place.

With regard to the size of focus stated, it might be suggested that it would be better to enlarge the size; but this would prolong the time, and allow greater disturbance to take place. Thus the result would not be so good. It is by magnifying them afterwards we get good copies. One of these on the table is about eight inches diameter; that is to say, it is magnified about seven and a-half times.

Occasionally I take photographs of the fixed stars, and have made pictures of the double star, Castor, and others, but, as a general rule, I devote my attention chiefly to the moon.

As in the production of the lunar pictures some few seconds of exposure are required, it is essential to have a clock-work driver to the telescope, capable of adjustment to lunar time, which differs from sidereal time. In my own telescope this is at present effected by altering the length of the conical pendulum or friction governor, thus altering the time of its notation (or double beat). And this plan, or some modification of it, is universal. My experience, however, has pointed out several inconveniences in thus changing the speed of the governor or pendulum, and it is my intention to make such alterations in the construction of the clock as will enable me to alter the going of the telescope without changing the rate of the pendulum. This I propose to do by substituting what is known as the disc and plate in mechanics for the wheel work now immediately connecting the machinery of the clock with the pendulum,—the disc and plate being capable of producing a variable motion according as the disc is nearer to or farther from the centre of the plate. The pendulum will, by the proposed plan, be driven by frictional contact, and having employed this system in other machinery, I feel persuaded that its application to the clock-driver will not be attended with difficulty.

Until very lately my lunar pictures were obtained by placing the sensitised plate at the side of the tube, opposite the diagonal reflector of my Newtonian telescope, and hence the light before it reached the plate had been twice reflected. I would remark that it requires a very firm support for the diagonal mirror of even a 13-inch mirror; hence the arm carrying this mirror was firmly screwed to the side of the telescope tube, and being immovable I could not make experiments in taking the pictures direct; that is to say with the light only once reflected. I have however within the last few months contrived a proper apparatus, and I now take celestial pictures at will, either direct or reflected, at the side of the tube, and it does not require more than a minute to change the apparatus to produce either result. So that I can make experiments to determine the relative actinic intensity of the light after one or two reflections. The experiments are still in progress, and have been began so recently that it is scarcely advisable to hazard a conjecture as to the result; but I may say that I am disappointed as to the increased rapidity of the production of a lunar picture by the direct method over the twice reflection method. And I am inclined to infer that Steenheil's result, as to the loss by reflection of the luminous ray, does not hold as regards the actinic ray.

The reflecting telescope has considerable advantage over the refracting one for celestial photography, on account of all the rays coming to a focus at the same place, which is not the case with the refractor; hence the focus having been adjusted for the luminous image, it is correct for the chemical image, and has not to be disturbed as with the refractor. I attributed much of my success to the employment of a reflector, while my fellow-labourers in the same field have used refractors.

The time occupied in taking lunar pictures varies considerably. It depends on the sensitiveness of the collodion, on the altitude of the moon and her phase. I have recently produced an instantaneous picture of the full moon, and usually get strong pictures of the full moon in from two to five seconds. Of course it is important to have the collodion in a right state, and to be prepared to operate with clean hands and not with dusty apparatus—the moon as a crescent under like circumstances would require about 20 to 30 seconds, in order to obtain a picture of all the parts visible at the dark limb.

Portraits of the moon equally bright optically, are by no means equally bright chemically; hence the light and shade in the photograph do not correspond with the light and shade in the picture; and hence the photograph frequently renders visible details which escape optically. Those portions of the moon, near the dark limb, are copied photographically with great difficulty, and it frequently requires an exposure five or six times as long to bring out those portions illumined, by a very oblique ray, as others apparently not more bright when more favourably illuminated. The high ground in the neighbourhood of the southern portion of the moon is more easily copied than the low ground, usually called seas, and I ventured in another place to suggest that the moon may have an atmosphere of great density, but of small extent; and this idea has, I imagine, received some confirmation from a recent observation of Father Secchi's, of the lunar surface polarising light more in the great low-lands, and in the bottoms of the craters, and not appreciably on the summits of the mountain ridges.

Photography brings out palpably to our senses several facts, which are of course well known, but we do not always think of them — for example, every 29 days we talk of the full moon. Now there is never a full moon visible except before or just after a lunar eclipse. At all other periods of the full moon we are unfavourably situated for seeing the whole of the illuminated hemisphere. The different apparent diameter of the moon at different times, dependent on her distance from the earth, comes out in unmistakable prominence. We are familiar with the moon's diurnal libration, in latitude and longitude, yet we fail to realise the great amount of disturbance unless aided by photography, when we see it palpably before us. Taking advantage of the libration of the moon, we get stereoscopic pictures which present to the eye what the Astronomer-Royal has said was the only experimental proof of the rotundity of our satellite. Mr. Claudet has told us that a dispute has been going on between photographers as to the proper angle for taking photographic pictures, and I infer that one side of the disputants would call my arrangement of the moon pictures to produce photographs unnatural. But, to use Sir John Herschel's words, the view is such as would be seen by a giant with eyes thousands of miles apart.

I have succeeded also in taking views of the planets. Excellent views of Jupiter and Saturn were taken. Amongst the views of Saturn exhibited, there was one taken at the period of the late occultation of Saturn by the moon, and on the photographic plate were delineated the planet and the moon — the former as just emerging from the moon's bright limb. The views of Jupiter were sufficiently large to give stereographic pictures. [With respect to Saturn, the pictures were so small as not to be visible in an ordinary stereoscope; but there was exhibited on the table a stereoscopic view of Saturn, composed of two photographic reductions from the original drawings of Mr. De La Rue, made with great accuracy in 1854 and 1856 respectively — the body of the planet standing out as a spheroid enclosed by a ring.]

Mr. De La Rue proceeded to give a description of the work performed at Kew Observatory (under the British Association), where, at the suggestion of Sir John Herschel, a photoheliograph had been erected, under the direction of Mr. De La Rue, at the request of the Royal Society. Many obstacles, which have been overcome only by repeated experiments, stood in the way of obtaining good pictures of the sun; and these difficulties arose in a great measure from the extreme brilliancy of the sun's image. Mr. De La Rue described the photoheliograph as follows:—[The illustration on the black board we of course cannot give, but Mr. De La Rue's description will be quite intelligible.] The instrument consists of a three-inch object-glass (made by the late Mr. Ross), corrected specially to insure coincidence of the chemical and visual ray. The image is not received directly on the sensitive plate, as is the case in taking lunar and planetary photographs, but is enlarged before it reaches the plate, by means of a secondary lens, which magnifies the sun's image to about four inches in diameter. The time of exposure is so short, that there is a necessity for a special contrivance for regulating the time of exposure. This is effected by means of a sliding plate placed just before the secondary lens. In this plate is a slit which is adjustable in width. The plate before taking the picture is held up by means of a thread. In this position the light is shut off from the sensitive plate. When the picture is about to be taken the retaining thread is set fire to and a spring pulls the plate rapidly across the secondary lens. The time of exposure depends on the rapidity of passage of the sliding plate before the secondary lens.

There have been recently some remarkable spots on the sun; and several views of that luminary were exhibited by Mr. De La Rue,

which showed the progress of these spots across the sun's disc, and the remarkable changes they had undergone during the intervals. The photographs also rendered evident the *faculæ* or bright spots on the sun. By taking advantage of the change of position of the sun's spots in the interval of one day, Mr. De La Rue had produced some stereoscopic views of the sun, by grouping together two photographs taken at that interval.

The PRESIDENT of the Section, Lord ROSSE, added some observations on the method of obtaining lunar photographs; and in relation to experiments made by himself, remarked that the results, so far as he had gone, were not nearly equal to those produced by Mr. De La Rue. He agreed entirely with Mr. De La Rue as to his use of a reflecting telescope; and also felt sure he had hit upon the right method of procedure in many of the very nice contrivances he had described to them.

The Rev. T. CHEVALIER remarked upon the interesting question of how to get rid of the great inconvenience of excess of light in taking photographs of the sun; and alluded to the experiments of M. Porro to overcome this difficulty by the application of polarised light for the purpose of getting the image.

There being a great deal of business for that day before the Section the discussion had to be broken off.

We find in one of the daily newspapers the following:—

"CHINESE INGENUITY.

"In the section of Mathematical and Physical Science, Sir D. Brewster exhibited a very curious specimen of chalcedony, in the interior of which was a landscape minutely depicted. The landscape was produced by the action of nitrate of silver, which had been insinuated into the interior of the chalcedony. It appeared that if this chalcedony was laid up in a dark room for four hours the picture would entirely disappear, and that upon its being exposed to the sun for ten minutes the picture would again revive—consequently that in this specimen there was not only evidence that a landscape might be insinuated into its interior, but also that light might be stored up for a time and again brought out.

"The specimen was shown to the members of the section, who examined it with much interest.

"The Earl of Rosse said that this was one of the many specimens of Chinese ingenuity which they seem to devise for the purpose of puzzling philosophers. Some time ago a Chinese mirror was sent to him by Mr. Emerson Tennent, on the back of which there was a landscape, which, by reflection, was exhibited clearly on the paper. He consulted books on the subject, the explanations given in which were not satisfactory to his mind. He proceeded to test the matter by examination, and found various inequalities on the surface, which had been made with a punch, and the surface again polished over, leaving it apparently smooth and plain.

"The specimen shown to the section belonged to the family of the late Lord Saltoun, and subsequently came into the possession of the lady by whom it was handed to Sir David Brewster. She at first imagined it was simply a piece of chalcedony such as might be employed in mounting a brooch. But on closely examining it, she observed the landscape. It was laid by for four years, by which time the picture had entirely disappeared; but, on being brought to light, in the space of ten minutes the landscape became again apparent."

[The opinion here expressed, that the phenomenon noticed evinces any proof "that light may be stored up for a time and then brought out," appears to be rather a singular *non sequitur*.—ED.]

NOTES ON THE PHOTOGRAPHIC EXHIBITION AT ABERDEEN.

[By a TRAVELLING PHOTOGRAPHER.]

As is my wont, I am about to supply you with some notes picked up at Aberdeen on my ambulatory professional circuit, which I know is a species of pabulum much to your liking. The photographic exhibition was held in a good-sized room, lighted by a large cupola by day and by gas during the evening. The walls were covered to the height of about eighteen feet and a-half with claret-coloured calico, which was stretched on laths. In addition to this wall space there were two screens running up and down the room, on both sides of which pictures were hung. A considerable number of unframed photographs were hung and glazed in the simple way adopted last year at Leeds.

The exhibition took place rather unfortunately at the season of the year when photographers are working in the field rather than exhibiting; still the collection was large, and contained many new pictures by our best photographers, including Rejlander, H. P. Robinson, Wilson, &c. Foremost may be mentioned the beautiful little pictures by Mr. Wilson, of Aberdeen, which for beauty and effect are not to be surpassed. Mr. W.'s instantaneous views would delight a Turner or a Claude. They are really pictures, not simple photographs. There is an atmosphere and breadth about them which is joined to great precision and clearness; and the vigour and tone of purity are admirable. The scenes from the Loch of Park may be considered as masterpieces of the art.

In taking a general survey of the whole collection, comprising 469 separate frames, the most striking impression is received from the bulky pictures, such as the *Cartoons of Raphael* and M'Pherson's *Rome*. Both have been exhibited elsewhere, and criticised in your Journal on former occasions. Although the cartoons, by Caldesi and Montecchi, attract considerable attention from their size and vigour of expression, I fear they are not generally appreciated by the casual visitor. Indeed it is impossible to see them at a single glance; they require to be made the object of a minute and careful study individually, and this cannot be done in the crowd of an exhibition room. I fear they are, like Milton's poetry, more praised than read or studied by the provincial public, especially those of them who have never seen the originals at Hampton Court Palace. Such expressions as—"Oh! ah! Raphael's Cartoons! wonderful things! pass on!" Of course *I* form a much higher estimate of these works than such critics, and do not mean to detract from the merit of these reproductions, about which so much has been already written.

No. 148, M'Pherson's *Rome*, is the next great attraction, both from its size and subject. It is a splendid photographic panorama of the Eternal City. This picture has also been formerly noticed by you.

Bisson Frères exhibit a series of beautiful Alpine views, being Nos. 170 to 175; and while looking at foreign photography, I must not omit to mention those by Ponti, of Venice. They are *Pallazzo Ducale, Venice* (339); *Bronze Gates to Campanile, Venice* (343); *St. Marco, Venice* (342); and *S. S. Giovanni e Paolo, Venice* (338). These are all characterised by extreme delicacy and sharpness.

I must now, after this general survey, return and go over the catalogue a little more particularly to notice what is new. The first that I come to are Nos. 12 to 16, a series of excellent views of that far-famed and beautiful ruin, *Elgin Cathedral*, by John Lamb, of Aberdeen.—Nos. 21 and 22 are interesting rock scenes about Peterhead, and the *Coast of Buchan* (stereographic), by George Dawson, of London. *Rubislaw Quarries* (218), by G. W. Wilson; ditto (104), by John Lamb, form intensely interesting geological studies for those interested in that branch of science.—No. 24 is a frame of stereographs, by A. Adams, of Aberdeen; two of them instantaneous views of the *Market Place, Aberdeen*, with crowds of people laying in their week's stock of provisions, such as eggs, butter, &c., and very well photographed. When I say instantaneous, I don't mean that they are done in the $\frac{1}{1000000}$ part of a second, which space of time a contemporary of yours desiderates as that occupied in taking an instantaneous picture. (?) It is to me nearly as difficult to grasp or get an idea of this infinitesimal space as to reach to eternity. Both are beyond the comprehension of man.—*Lavinia* (26), and *Nearing Home* (27), by H. P. Robinson, Leamington, are not quite so successful as the compositions of Rejlander, but deserving of notice by artists especially, who do not appear to take so much advantage yet of the photograph's assistance as they might, and will do by-and-bye.—No. 45 is a series of very beautiful stereographs by Ernest Edwards, with more half tone and delicacy than are usually met with in this class of subjects.—*The Old Mill* (54) and *View on the Don* (55) are by the waxed-paper process, by J. F. White, Aberdeen. The latter especially is fine in composition.—Nos. 65 to 69 are foreground studies by Messrs. Ross and Thomson, Edinburgh. They are by the wet collodion process. *Cupid* (69) is a beautiful boy, sweetly posed, with fine expression and delicately caught, a perfect model for such a picture. These gentlemen do not exhibit in Edinburgh, their local *habitat*, but they have abundant material, and of the first water, both as regards splendid composition, excellent manipulatory skill, fine tone, and exquisite detail. Their quota is quite superb. Nos. 106 to 135 are also their productions (eighteen or twenty of which were taken this season), consisting of bramble, furze, nettles, dock-leaves, fox-glove, and other wild flowers; as also studies of stems, with and without branches, of the sycamore, lime, larch, beech, ash, and willow trees; mountains and glens of Caledonia, &c. Pity that such a collection should be lost to the Edinburgh public by the mal-arrangements of the Photographic Society of Scotland! These productions have a peculiar softness, not matched by any other single figure studies in the room. The nearest approach to them is perhaps by Mr. Rae, of Banff, in his portrait of the *Countess of Fife* (327), which has been placed in the centre of one of the screens, and is really a beautiful and successful photograph.

In No. 74 there is a capital sample of photography in a path not hitherto much trodden, where its aid will be of incalculable service. It is a portion (so to speak) of a *Locomotive Engine and Tender*

constructed for the Viceroy of Egypt, and gives an excellent idea of its covering and ornaments — almost of its colour. "*Puffing Billy*," *the first locomotive used in the north of England* (72), is also worthy of notice. Both are by T. Worden, Newcastle. — Nos. 96 to 99 are small vignettes of castles in Banffshire, by A. Rae, printed with great taste.

The *Bridge of Feugh* (153), and *Reach of the Dee* (155), are the only two I notice of R. Fenton's, and I am sorry to see they look a little yellow and faded. The same remark applies to a very interesting panorama of Algiers; but now that old hypo' has been thrown to old Harry, I am confident that we shall have fewer complaints on this subject in future.

Nos. 176 to 185 are some interesting subjects from Orkney, by the Earl of Caithness; and although the negatives appear to have been *rather* thin if anything, still for *a Lord* they are very creditable productions.

Nos. 230 to 242 are enlarged photographs from microscopic objects. To unscientific persons these appear to be of great interest, and more instructive and useful than the micro-photographs taken by the other end of the instrument. I marvel that this branch of photography has not been more largely cultivated, especially by amateurs.

Next in the catalogue comes a long list of portraits of public men, by Maull and Polyblank, which do not call for any remarks, as they have been all previously exhibited. The shrewd intelligent look of Sir D. Brewster has been beautifully caught, and the quiet dignity of the Earl of Rosse—not a King-made Peer, but every inch a Lord in the proper sense of the term.

There are also some good portraits by J. Valentine, Dundee, especially Dr. Nimmo (276), which is good in tone and successfully posed.

Two groups, each containing about a hundred heads of canny Aberdonians, are by G. W. Wilson, of Aberdeen, whose stereographic slides are so much admired by the editor, and well they may be, for they are peerless in this region of the globe, and far eclipse all the misty, muddled, waxed-paper be-medalled productions of the Scottish Society. — There is a frame of excellent portraits by Mr. Moffat, Edinburgh, which have been previously exhibited and favourably noticed by you on a former occasion.

None of the great London limners — as Claudet, Williams, or Kilburn — have sent any specimens of their productions.

Nos. 294 to 299 are *Sea and Cloud Views*, by G. W. Wilson, which more profitably occupy the space than a row of heads which have little interest but to those who know them. These were specially noticed by you in January last, and maintain their superiority to any in the same line yet produced.

Old Tom, the Highland Gaberlunzie (303), by Horatio Ross, is a very quaint successful sketch of a picturesque Highlander.

The Wayfarer, by Rejlander, is a large figure study, posed as Rejlander *only* can do it. The detail of this picture is exquisite — the veiny hand, the wrinkled forehead, the plaited smock, are perfection, while the general tone of the picture I think surpasses anything he has done before. The figure is seated by the wayside, in the attitude of eating fruit, while the hat is reverently laid aside, and the head bared during the scanty meal, and is a good representation of Walter Scott's "Old Mortality." The brown felt hat reclines on the bundle, while the staff — his travelling companion — is hooked through the loop of the tie. — "*Speed him well*" is another composition from the same hand.*

Nos. 315, 316, 331, 334 are views in Edinburgh, by Taupenot's process, by W. D. Clark. These were exhibited previously in Edinburgh, and are the finest photographs I have seen by that process, having nearly all the softness and delicacy of wet collodion.

No. 410 is a series of portraits taken in 1842, and fixed by immersion in weak water of ammonia, by R. Adamson, St. Andrew's, and are not the least interesting portion of the Exhibition. There are also some portraits taken by Fox Talbot's original process, and after *seventeen* years they are as fresh as if they had only been done a week ago.

In another room there are some pieces of apparatus exhibited, in the shape of cameras, baths, &c., by Murray and Heath, Skaife's pistol camera, as well as some of De la Rue's wonderful photographs of the moon, and some excellent achromatic stereoscopes by Smith, Beck, and Beck, of Coleman Street, London. It is quite a treat to look at one of Wilson's fine stereo views in one of these.

But I must now finish, as my notes are already too long, and if I have missed any thing worthy of peculiar notice, you must blame the crowd and not me.

SEL D'OR.

* These two productions of Mr. Rejlander have very recently been noticed by us at length. — Ed.

Meetings of Societies.

LIVERPOOL PHOTOGRAPHIC CLUB.

The ordinary meeting for the month was held at the rooms of the Liverpool Photographic Institute on Tuesday evening last.

Mr. Keith exhibited the proofs of twelve exceedingly fine views that he had taken of that majestic ruin, Furness Abbey, in company with two friends, in the previous week. Though so numerous, and taken in only two days, and several of them by means of unusual exposure, it would be impossible to particularise which was of most singular beauty, — even up to the edges of the plates, though so large as twelve by ten inches.

A remarkable peculiarity was elicited during the taking of these views, namely, the prolonged exposure that wet plates were capable of without the haloide salts crystallising on their surface. As the light gradually faded, the exposure was so much extended that the later pictures were fifteen minutes in the camera, beside the time occupied in coming and going through the grounds from the operating tent (in this case a very cleverly contrived barrow) to the camera.

Mr. Keith also submitted to the members several pieces of paper from the mills of Messrs. Pirie, of Aberdeen, which had been expressly manufactured for this Society. It was exceedingly fine in its surface and equable in its texture, but pronounced not to be so free from spots nor so nearly what is required as some that was shown by Mr. Corey, from the mills of Messrs. Hollingsworth, also prepared for this meeting. Pieces of each were distributed for the ultimate judgment of the members.

At a previous meeting Mr. Burgess, a former member of this Society, gave an animated description of the experiences he had had in a recent voyage round the Cape, in the *Imperatriz*, for the purpose of laying the Red Sea cable, the major part of which had been successfully performed under his direction, as the sole electrician on board that ship. After describing his departure, and many experiments subsequent to his sailing from hence, he says:—

"At Madeira the results were much the same as in this country, but I found no one at Funchal practising photography on our outward voyage, though one made his way there before we returned. A few days after leaving the Island light was much quicker in action, and a good negative might be taken in two or three seconds in the shade.

"At the Cape of Good Hope (Cape Town) the light was to all appearance very good, but the time required was nearly one minute with single lens. Here I found it very difficult to get large plates 10×12 free from spots. Filtering the bath did not much improve it. The contrast of light and shade is very marked, for a great number of the buildings have flat dull roofs and white walls, and the mountain tops were enveloped to some extent in mist. I found here a number practising the art — one an English chemist, who gave me every information. From the Cape we proceeded to Aden. Here the contrast of I may say everything was considerable—from a fine, rich, and beautiful place, to a bare, barren, volcanic soil, nothing but sand and rock, with intense heat, and a dazzling sunshine, in which you might say fifteen seconds would be sufficient exposure. From the accounts of photographing in the east, I expected a minute would be sufficient in the bath, the thermometer being about 100°, but I found five minutes quite little enough. Then came the exposure: I gave thirty seconds but found scarcely a trace of anything upon developing; the next I exposed one minute and found not so bad a positive, but when I attempted to wash it the result was a plate covered with chloride of silver. After a few trials I found it of no use to proceed, as the water was so salt I could do nothing. There is no water here but what is condensed from the sea, and very bad it is. It is quite impossible to get any rain water, for the most rational of all reasons, it never rains in this place. I had to return to the ship and bring water the next day. Our own from the ship was salt water condensed, but it was very good.

"On getting to work next day I found two minutes with a large stop in rather little enough time for exposure; the light acts very slowly, from the angle of reflection being nearly vertical. It is very yellow, and the sand does not add to the reflection. The buildings are much the same as the sand, so it is difficult to discern a distinct outline, even with the eye. I also found here a countryman, a photographer. His experiences exactly agreed with what I found. The best negatives were taken late in the day; and early or late, I have no doubt, would give the best pictures. Proceeding up the Red Sea as far as Suez the results were much the same, with Thomas's collodion, Ross's lens, new bath and collodion, which

came overland. I found by adding oxide of silver to my bath, as formerly recommended by Mr. Glover, it in a great measure prevented specks or spots. I had made my own collodion, and I liked it better than any other; but you here see pictures taken with both. On returning home I found that several things were affected by the sea. Test papers were quite red; gun-cotton would neither dissolve nor burn; printing paper was also to an extent spoiled. I do not think collodion suited for such very hot places; I believe albumen would be much better. It is very difficult to get apparatus to stand on board of ship, where agitation is constant and damp prevails. On land every place is hot, thermometer 100 to 130 deg., and everything is roasted."

CHORLTON PHOTOGRAPHIC ASSOCIATION.

THE first meeting of this Society after the summer vacation was held at the Chorlton Town Hall, on Wednesday, the 14th ultimo, Mr. HOOPER in the chair.

The minutes of the last meeting having been read and confirmed,

The SECRETARY said he had received from Mr. Keene two photographs as a contribution to the Society. He begged to move "That the best thanks of this meeting be given to Mr. Keene for them."

This was seconded by Mr. WARDLEY and carried unanimously.

The CHAIRMAN said the photographs were very remarkable for clearness and absence from stains in the negatives, and were as good specimens as he had seen by the Fothergill process. He would ask the members to contribute to the portfolio of the Society any good prints that they might have negatives of.

Some members complained of the difficulty of working this process with certainty, and said they could depend better on collodio-albumen; others thought it only required care to succeed.

Mr. NOTON exhibited a machine for frothing albumen, which would be very useful where a quantity was required. He said the albumen when well beaten was much more limpid than when that operation was only partially done; and any gentleman was at liberty to try the machine for himself at his own house. Mr. Noton also exhibited several photographs, taken on dry albumen, which were very well defined, he said they had received a long exposure. He also showed to the meeting an arrangement for altering the stops in the lens from outside the tube; the stops were square, but produced no effect different from circular ones.

Mr. WARDLEY exhibited a new camera, with folding body, very compact and portable, lately introduced by Mr. Mudd; also a photograph taken by it, with an orthoscopic lens, exceedingly sharp to the edges and the lines very perpendicular.

Some conversation on the strength of the printing bath resulted in a general opinion that sixty to eighty grains of nitrate of silver to the ounce, kept up to the original quantity by additions of a 100 grains solution to the ounce, gave as good results as any stronger solution, but might not print so quickly.

Some members having seen the waxed-paper negatives taken by the Chairman, and feeling that it is desirable to work larger pictures than the stereoscopic ones, which are exhibited of all kinds in such profusion, requested that gentleman to state his mode of manipulation.

The CHAIRMAN said that he should be glad to read a paper on the subject at the next meeting of the Society.

The usual vote of thanks to the Chairman concluded the business.

PHOTOGRAPHS TAKEN FOR GOVERNMENT INSTITUTIONS.—To enable the public to derive full advantage from the photographic negatives made officially for the Science and Art Department, from rare and valuable objects in public and other collections, British and foreign, the Committee of Council on Education has caused an office for the sale of photographic impressions from such negatives to be established at the South Kensington Museum, which will be opened on the 3rd of October. Photographic negatives, made by order of the trustees of the British Museum, and for the War and other Government offices, will also be sold. The tariff for unmounted impressions will be as follows:—A single impression, the dimensions of which contain less than 40 square inches — *e. g.*, 5 inches by 7, or 4 inches by 8 — 5d. Above 40 square inches, 2½d. should be added for every 20 square inches or under. A detailed list of the objects photographed is printed, price 2d. The department does not charge itself with the mounting of impressions, as the public is able to do this for itself.

NOTES OF A PHOTOGRAPHIC TOUR IN THE HOLY LAND.

No. VI.

A FEW days ago we rode down to Jericho and the Jordan by the road over the Mount of Olives, through Bethany, and thence among wild hills. This seems to be the ancient road, and I cannot in my rides find another which would throw doubt on this idea. Doubtless this is the path which the Saviour alluded to when he related the parable of the Good Samaritan, and which he often passed over.

Travelling in the Holy Land must be done entirely in the saddle. The pace is always a walk, and the distance travelled in a day is seldom more than twenty miles. This is when women and children are concerned. For my part I cannot submit to this snail's pace, but like to fly as swiftly as the swiftest of Arabian horses can carry me. A free rein, a knee pressed firmly in the saddle, a keen eye and a cool head, are all that is required to make me equal to a Bedouin Arab on horseback.

I came here under the idea that I should taste freedom, the freedom of the desert, and I turn my horse's head as it suits me, now here, now there, taking my chance of finding a bed, or at least sleep in the Arab's tents, and I can even take my rest when the black tent is inaccessible.

I started off early in the morning. Our tents were struck at daybreak. The Valley of Jehosaphat had a deserted appearance, desolate and mournful, as it usually is, when I looked into it from the winding road that goes around the eastern side of Mount Olivet, and I missed the familiar home that I had occupied so many days. We went through Bethany at a gallop, and were soon in a dark ravine among the hills, down which our course lay. We got lost, but how it happened I know not; but we did get lost, and that too in the worst of roads, celebrated for its thieves now as of old.

We passed the night in a queer place. I think it must have been once a castle of the Crusaders. It is a fine ruin, crowning a lofty hill, and commanding a vast prospect. No foot of civilised man can have been in it, except it be of wanderers like ourselves, for centuries. Seeing it from a distance, I pressed forward to it as the night fell, crossing three of the deepest ravines and as many sharp ridges before I reached it.

In the grand court of this old castle we found a pile of dry brushwood, to which we helped ourselves. It had doubtless been collected by the Bedouin women. If ever I meet them I will pay them. In a little while we had a blazing fire in the chief room of the old building. I call it room, for such it once was, though now the floor is turf and the roof is sky. The scene would do to paint but would make nothing as a photograph. I slept soundly under the side of a rock, a long stone which had once done duty in the wall, but now served as a wind breaker to a houseless wanderer. John grumbled occasionally, but upon the whole we did well. I have seen worse quarters.

In the morning we found the road, striking it near a ruined khan, and in three hours' time opened that splendid landscape, the Valley of the Jordan and the Dead Sea. Far down below us it smiled like a valley of heaven, rather than the deep sunken place of the curse of God.

The solitary tower which marked the site of the village of E'Rihah, the sole representative of old Jericho, was visible in the plain. The gorge of the brook Cherith on our left went plunging down and down to the valley, where it was spanned by two ruined stone bridges of ancient days. All was grand, magnificent, and solemn around us; all was exceedingly beautiful, calm, and glorious beyond, even to the mountains of Moab, that rose majestic across the Jordan.

We descended rapidly to the plain, emerging from the gorge of the brook on a high platform, which occupied the western side of the valley. This let us slowly down to the true valley level, and a gallop of half-a-mile to the northward brought us to the Fountain of the Sultan, where we pitched our tents.

The fountain, a noble gushing stream, is doubtless that healed by Elisha, when its waters were bitter. It lies a mile or more from the modern village, the representative of ancient Jericho. I think it probable, however, that the ancient city was near the fountain; for ruins of old buildings lie scattered here and there all along the hillside. The high bluff of the mountains which overlook the fountain is dignified by tradition as the place of the termination of the forty days' temptation in the wilderness, and the high hill whence the Saviour saw the kingdoms of the world and the glory thereof.

Jericho is a desolation. It lies as prostrate as when the walls fell before the trumpets of the children of Israel; nor from that fall to the present day has any man, king or slave, prevailed to

build again the accursed city. Herod's city was not on the site of the ancient Jericho, but nearer the mountains. The plain is four or five miles broad between the hills and the Jordan.

Early in the afternoon we were in the saddle, and rode at a gallop across the plain to the sacred river, reaching it at the spot where the pilgrims come annually to bathe and wash away their sins. It is a sight well worth coming thus far to see.

The pilgrims who throng Jerusalem at Easter are chiefly Armenians, though there are many Latins and Greeks. They form a vast assembly, and one of the requirements of the pilgrimage is a bath in the Jordan, and a dipping therein of certain garments wherein they expect to be buried. Indeed this is the great end of the pilgrimage. Hence the camp-ground of the pilgrims and the scene at the river are among the most interesting views that a travelling artist can take away with him.

If the Jordan could so wash away sin, I am a clean man, soul and body; for I have bathed seven times in its icy water. It comes down cold and fierce from Lebanon and the Sea of Galilee, and its waves are as chilly as the waves of that river it is so often made to typify.

Perhaps I have lost the blessings of the Jordan by my many dips in the Sea of Death. I cannot now stop to describe the Jordan Valley nor the Dead Sea. We rode down to the shore of the sea in the twilight: Hassan was anxious lest the Bedouins of the Ghor should take the night to attack us, for we had paid no tribute, and were therefore proper prey. I had invited the Sheik of the Ghor, however, to meet me in the evening, intending to pacify him with an appropriate backsheesh; but he might be impatient, and it was hardly safe to trust ourselves out after dark in the valley.

We flew like lightning across the dry dusty plain, over which the Jordan had but lately swept in its spring overflow — pausing on the shore of the Sea of Death only long enough to taste its bitter waters, and to see the long black shadows of the mountains of Engeddi stealing over and taking possession of the sea, with a pomp that signified how totally it was given over to darkness and the powers thereof — over the plain to our tents by the Fountain of Elisha.

The Sheik of the Ghor Bedouins and a dozen of his tribe were waiting for us at the camp fire. Wild, fierce, and fiendish did they verily appear in the flickering light. But the Jordan Arabs have not had such a feast for years as I gave them. I had a sheep killed, and they ate like lords (lords eat only mutton in the East); and when they were filled to satisfaction, I made a compact with them, then and there, swearing eternal amity between all the Bedouins who inhabit the Valley of the Jordan and all the followers of the high and glorious Sheik of Lancashire who shall henceforth visit the valley aforesaid. Much good may it do you, oh traveller! But be warned: if you do not make treaties on your own account with mutton and with money, the hounds of Ishmaelites will take no evidence that you are included in former treaties, except such evidence as you may be able to give out of the muzzles of your revolvers.

The next day I loitered around the head of the Dead Sea. Shall I repeat to you the often-told stories of its strange character? How it floated me high up when I bathed, and stung me furiously in my eyes, and in every pore of my skin with its sharp acrid salts? I was glad to wash off the glistening salt which a morning bath left on my skin, by dipping myself for the eighth time in the Jordan.

Practical Instructions on Coloring Photographs.

By Alfred H. Wall.

CHAPTER V. *(continued)*.

THE HANDS.

A little white, to strengthen the shining lights upon the knuckles, is first used; then a little carmine for the nails, knuckles, and other pinky portions; and then a little pale blue for the veins, leaving the other tints for the present.

DRAPERIES.

Begin with the lighter folds and darken as you soften into the shadows; in silks and glossy fabrics put in the highest or whitest lights with a tint very little removed from white, by which the effect will be much enhanced in the finished picture.

BACKGROUNDS.

If your picture is small, a plain background with a light about the head to secure breadth is best. (See Maxims No. 16 and 52). If a larger picture you may introduce a background of clouds, sky, and distance, with very good effect; curtains and architectural objects are also frequently introduced. (See Maxims 50, 51).

SKY AND DISTANCE.

If the positive has a darkish grey background, it will with a few touches of various greys (greenish, brownish, and bluish), be converted into a very artistic "bit of distance," the horizon tint being used to form its boundary. Work this tint (the horizon) upwards into a pale warmish grey, and this again into the high lights of warm white, or small fleecy streaks of fleshy clouds, or into the azure. If desirable, the sky may be composed entirely of pale and dark, warm and cold greys, which form a very effective background to a vigorously-marked head or military costume. Curtains are seldom nicely managed; but architectural objects may be touched in with greys and browns, leaving the surface of the plate (if dark enough) to form the shadows. Having finished the first colouring, take a clean well-pointed pencil and remove any stray colour which during your progress may have obscured the shadows or outlines.

THE SECOND COLOURING.

If you are using the new absorbent colours, breathing over the plate and permitting the moisture to evaporate is sufficient preparation; but if not, your next step is to varnish the picture, as the first colouring is on the collodion itself — for which reason, by the bye, great care should be used to avoid scratching the plate by rubbing it too hard, or suffering the quill or tin ferule of the brush to touch the surface.

The varnish having dried, or the moisture evaporated, as the case may be, the carmine — strong or faint as may be necessary — is then applied upon the cheeks; and will most probably also be required, more or less, upon the nostrils, bridge of the nose, lower portion of the brow, and the chin. If a faint blush of colour be required for a very delicate complexion, use a little of pink No. 1, with or without a touch of carmine; or should the pure carmine be too bright and powerful, combine with it a little of flesh No. 3; or again, should it approach scarlet, add a very slight touch of pure orange. Take the colour labelled "horizon," and with white, mix a warm pale tint to strengthen the high lights, making it more or less white, or more or less yellow, as may be most consistent with the local colour of the flesh; and this done, the retiring shadows may be slightly and carefully touched with a warm grey, compounded of flesh No. 3 and green No. 2. Finish the hands with flesh No. 1 and pink. Repeat the colouring of your drapery, avoiding the darkest shades — using, however, a pale tint of the local colour for the highest lights instead of the light tint recommended as a ground to strengthen their effect in the first colouring.

TO COLOUR A VERY DELICATE FAIR FACE.

Use white for the high lights, place the pale horizon tint next to this; then blend this into a third tint, compounded with the second and a little carmine; and this again into a fourth tint, composed of flesh No. 1 and a little blue. This treatment should also be adopted for ladies' hands, necks, and bosoms.

TO COLOUR A VERY DARK FACE.

Use for the high lights a strong tint of orange and white, blend this into a second tint of orange and carmine, and this into a third, of warm brown, orange, and carmine, reducing the whole, if too brilliant, with a tint composed of carmine and green.

THE EFFECT OF VARNISHING

Is to modify and subdue the first colouring — which should therefore be more brilliant than the second — and according to the quality of the varnish, to lower the whites, which consequently require some few light touches of white to indicate (as the photograph itself seldom does) the high lights of linen or white drapery. Certain colours, also, are affected to no small extent by the varnishing, some being rendered very much too strong, others being almost destroyed. Those least affected are the yellows, reds, and greens. A little practice will however best explain this difficulty.

SCARLET COATS AND JEWELLERY.

In colouring a scarlet coat with powder colours, your great difficulty will be found in preserving its folds and roundness, the opaque nature of your pigments* destroying the half-tints and shadows in the same degree as they produce the force and brilliancy damanded for a truthful effect. In this case, therefore, more than common care is requisite. Select a colour for your high lights first. This should be a scarlet of a somewhat orange tone; and be

* To claim transparency for powder colours, in themselves, is a common mistake. When ground to an impalpable powder and slightly applied, they, by the mere fineness of their particles, *seem* almost transparent, but of course cannot be really so.

careful that in obtaining it you use *no white*, which would effectually destroy the purity of your colour. The next colour is the local one, viz., scarlet, the next carmine; and the shadows are coloured with crimson, which upon *the darkest shades* should be applied *before varnishing only*. You will find that the local scarlet is a colour somewhat difficult to meet with. I obtained a set of very excellent scarlets in a box of the new colours introduced by Messrs. Reeves & Sons.

Jewellery is too generally touched with the gold and silver sold in shells, which, unless used with no little skill, produces a very coarse and untruthful appearance. The simple fact of the jewellery thus touched having lights and shadows of its own continually varying with the light in which the picture may be placed, and perfectly independent of the light and shade upon the image itself, should denounce the vulgar taste displayed in its use, and confine it to the studios of a class of "photographic artists" who laud the fact of its being "real gold" to their sitters as an inducement for the outlay of "tuppence" more for a ring, or "sixpence" for "a gold chain." I have seen a minute touch of the silver applied with singularly good effect to the spark of light in the eye, but it perishes as the silver blackens. *Gold* is best executed with water or oil colours. In this case take Naples yellow No. 2 for the high lights, yellow ochre for the local colour, bistre and burnt sienna for the shadows, and orange chrome for the reflected lights. *Diamonds* are best represented by a vividly bright touch of pure white (water colour), and coloured stones by the same upon the local colour, opposite a touch of this local colour mixed with white, to represent their transparency. For *silver* use white for the lights upon a ground of warm pale grey, with somewhat warmer shadows. For *pearls* use a brilliant touch of white, very minute, diagonally opposite another similar touch of white and Naples yellow. *Coral* may be painted in with lake and vermilion for the local colour—pure lake for the shadows and pure vermilion for the lights, the highest lights with the same and a little white.

Letters to a Young Photographer.

No. XX.

MY DEAR EUSEBIUS,

Not every bird that sings is a nightingale, nor is every one who paints an artist. I wish particularly to draw that distinction. In most boarding schools, young ladies are taught to draw and paint, with what result, in an artistic point of view, I need not stop to dwell upon: their productions fitly rank with those other artistic results of young ladies' ingenuity — crochet, samplers, and Berlin wool. I cannot recognise a man to be an artist unless he possess a natural genius for his vocation: we may produce any number of painters as we can adepts in any other calling, be they tailors, carpenters, or shoemakers, by "sticking to it" for seven years or more. Take any boy of average talent, and teach him to draw and paint, and he will, by diligent plodding, manage to eke out a subsistance. Every year his crude productions will help to cover the walls of the exhibition room, and if the subject be "taking," may sell; but shall we profane the word by calling him artist?

I have been a regular attendant upon the Royal Academy Exhibitions for a quarter of a century, and I am lost in wonder when I reflect that, of the many thousands of pictures I have seen there, how few have excited more than a passing tribute of admiration—how few have taken hold of the imagination, or left a strong impression on the memory. One exhibition is so like another that when you have removed the productions of the few who are worthy to be called artists, the rest is mere manufacture, the production of painters who, because they paint, arrogate to themselves the title of artists, a title to which they have as little claim as the author of "Hoop de dooden doo" has to be called poet.

Not every rhymster is worthy to be called poet, neither is every painter artist. I maintain that the true artist, like the poet, is born, not made. Culture is, of course, required to develop and perfect both; but no amount of culture will supply the place of natural genius. We value a picture or a statue for the thought it utters; the execution is a secondary consideration. Some of the greatest artists that ever lived have lacked the power to employ the highest mechanical resources of their art; but an idea extensively prevails now-a-days that execution is everything, hence the excessive mannerism of most of our artists, and one-half the time of many painters is spent in searching for the "lost medium" of the old masters. In their simplicity they think it was by some mechanical agent, some oil or pigment, that Titian, or Reubens, or Rembrandt, became as great as they were.

I have instanced Gainsborough as one of whom the British School of Art has great reason to be proud. His execution may be objected to, but that is of little account in connection with my subject; I maintain that, in all the intellectual qualities that constitute the true artist, he is worthy to rank with the greatest of any country or period of history. It is not in his landscapes or rustic subjects that his peculiar excellence is shown, but in his portraits: he is one of the very few that could portray the soul as well as the body of his subject, the spirit that informed the features, the character, the everything that animates and gives life to matter. I think I have never seen this quality so strongly exhibited in any other artist, besides Raphael. Gainsborough fell upon evil times, when the pursuit of art was a mercenary calling, and his genius, in consequence, never had fair play.

The painter's inspiration, like the poet's, comes from within. He can utter only the thoughts that lie within, and his works speak to us, and command our attention, in proportion to the depth, power, and extent of his thought. Now it is easy to produce any given number of pictures which utter no thought whatever — which are of the earth, earthy; but let not such works be ranked among the productions of true artists.

We have thoughtful artists among us, whom it would be invidious to name: whose works are prized at their true worth; but then, again, there are others as highly esteemed by the connoisseur and the public whose chief merit lies not in the thought, but in the dexterity, the sleight of hand, the execution, of their works. The latter enjoy only an ephemeral popularity, and must in due time find their proper level. The former have had to wait patiently for their merit to be recognised.

Art is a representation: it represents by means of outline, form, or relief, and colour. The power and resources of outline, as a means of communicating the thought or idea, is shown in great perfection in the pure classicism of Flaxman, and in the romanticism of Retzsch and the American Darley.

In the outline illustrations to "Margaret" the power of expression by outline is carried to a degree of perfection which leaves nothing to be desired in delicacy and completeness of representation. They place Mr. Darley in the foremost rank among living artists.

In the representation of form or relief, apart from colour, we have rare examples in the works of Kaulbach. Witness his "Battle of the Huns," his "Fall of Jerusalem," his "Prime of Greece," his "Reynard the Fox," which would gain nothing in expression by the addition of colour.

An eye for colour cannot be acquired any more than an ear for music: it is a natural gift which in part supplies the place of the knowledge of nature's laws. Where this faculty, or eye for colour, is deficient, the painter, guided by a knowledge of the laws of the harmony and contrast of colour, may attain very satisfactory results, although he may never become distinguished as a colourist, like Titian or our own Turner. This subject of colour is so vast and profound that I must defer its consideration till my next. It is governed by laws of its own, but these laws were never investigated until within a few years; you will find the result in the excellent work of M. Chevreul.

I promised to speak of *chiaroscuro* in this epistle, so I must bid adieu to digression. By *chiaroscuro* we understand the complete representation of all the lights and shades existing in the model. This is the most complex and difficult branch of the painter's art; as it not only embraces the variations of white light and shade, but also the reciprocal action of coloured lights upon the local colour and upon each other. It is so difficult that few painters have sufficient patience to study it. Most of the Exhibition pictures are deficient in it. You will find the *chiaroscuro* in the various figures composing a picture treated as if each figure were isolated, and the reciprocal action of the reflections upon each other neglected. Without the aid of *chiaroscuro* art would be powerless to represent light. The most luminous pigment is but mud in comparison with the brilliant light reflected from a body illuminated by the sun's rays. You may exhaust your stock of whites and yellows, but you will never succeed in producing light. But paint in *chiaroscuro* all the delicate and obscure reflections suggested by art, and you immediately inundate your picture with light.

In this branch of art Rembrandt is the master *par excellence*. He preferred to represent its effects because he felt them better than any one else; and by uniting study to feeling, and practise to inclination, he has hitherto remained inimitable in *chiaroscuro*.

Chiaroscuro is the principal source of light in the art of painting—the rich mine which the Flemish painters have so skilfully worked; painters who were as great in light as in colour; the first painters

in the world in these respects. It is also of itself a source of poetry; it reveals the hour of the day, its hue, and physiognomy. It enlarges the scene beyond its natural limits. It enlivens the shade and reveals the mysteries of darkness. It is the chief quality in interiors, and an important resource in every kind of scene.

Modern art has greatly cultivated *chiaroscuro*, its resources and effects. Witness the wonderful results in the *diorama*, and in scene painting. It is in the representation of *chiaroscuro* that the photographic art excels and triumphs.

Compare the most finished drawing you can obtain of any object or scene with a good photograph of the same, and you will see how immeasurably superior the photograph is in representing all the various delicate features that constitute *chiaroscuro*. Of course the subject must be suitably selected with regard to colour, else the accuracy of the effect may be marred. The complexities of *chiaroscuro* are so great as sometimes to lead the artist to despair of representing them. *Chiaroscuro* is not regulated by uniform laws like simple relief. An object can be drawn from memory, and very accurately too, by one possessing a knowledge of the laws of relief; but not so in *chiaroscuro*, when all the effects of reflection from surrounding objects influence the model, and render it necessary to study it on the spot.

Suppose the model to be a sphere submitted to these influences, its relief will always express a sphere, but its *chiaroscuro* will vary as you move different bodies around it or move it among them.

If you paint two strips or bands in different colours in flat tints, and place them in contact, an effect in *chiaroscuro* is produced—the bands do not appear flat, but graduated from the line of contact, where there is a contrast of tone or of intensity as well as a contrast of colour, heightened by contact also.

Photographic Glossary.

Thermometer—An instrument for measuring the temperature of bodies. It consists of a slender glass tube, hermetically sealed, having at one end an enlarged receptacle for containing the fluid, mercury or alcohol, with which it is filled, and which is acted upon by heat.

Thermometer Scale—Two points are marked upon the thermometer tube, one at the temperature of freezing water, the other at its boiling point. This space is variously divided: in the centigrade scale, that used in France, it is divided into one hundred degrees; in Fahrenheit's scale, that used in England, this space is divided into one hundred and eighty degrees. The zero of the centigrade scale is the freezing point of water; that point on the Fahrenheit scale is marked 32°.

Tinctures—Solutions of various substances in alcohol or spirits of wine are called tinctures.

Toning—A photographic process by which the image formed by chloride of silver is coloured of various hues of violet and purple by chloride of gold, &c. Numerous formulæ have been at various times given in this Journal, the best of which is that proposed by Mr. Maxwell Lyte.

Tripod—A piece of apparatus constructed for supporting the camera obscura. It is of various forms and patterns, but the principle is the same in each. Any three-legged support may be called a tripod.

Tripoli: Tripoli Powder—Fossil infusoriæ used for polishing daguerreotype plates, glass plates, &c. It appears to consist principally of silex.

Turpentine—An exudation from the pine tree. By distillation and rectification it assumes the form of a white, transparent, volatile liquid, of a peculiar odour. It is very inflammable. It dissolves wax, the resins, &c., and is a useful ingredient in varnishes. When submitted to a higher rectification it becomes lighter and more volatile, and is called camphine.

Foreign Correspondence.

Paris, September 27, 1859.

On a former occasion I mentioned that some very curious and unexpected results had been arrived at in M. Nièpce's experiments on the chemical influence of light upon solutions of starch, &c. In conjunction with M. Corvisart, he has published a report of these experiments, which, it appears to me, are of sufficient interest and importance to form the subject of a communication to you. They state the following propositions, and some of the conclusions derivable from them:—

Solar light, by its own peculiar action, modifies and transforms certain amylaceous substances and some of their educts.

The sole but prolonged action of light transforms starch, pure and dissolved, into dextrine and even sugar. But light first profoundly modifies the nature of starch, and changes it into a substance resembling inuline—which, when cold, is quite insensible to the action of iodine—but which otherwise differs from it in not reducing the salts of copper and silver in presence of ammonia, and it does not turn the plane of polarisation. This change may be produced in a solution of starch after a solarisation of six hours in the month of July or August; but it often requires fifteen hours' solarisation to produce a complete effect. Starch, protected from the solar influence, but exposed the same length of time and in the same place, undergoes no change, but immediately becomes blue by the action of iodine.

This transforming action is impeded by the lactates, and by citrate of iron: it is entirely prevented by bichloride of mercury.

The potasso-ferrié-tartrate augments the transformation, both in the light and in the shade, but at least one-third more in the light.

Nitrate of uranium powerfully favours the action of solar light, which becomes five, six, and even seven times greater: it is also more rapid, and the quantity of starch transformed is greater. The three kinds of transformation of starch indicated above take place:—First, iodine ceases to colour the cold solution of starch, but there is no polarimetric deviation, less appearance of sugar, and very little dextrine. The same amylaceous substances, protected from light but exposed in the same place, remain unaltered.

The acids of the preceding salts in feeble solution (two per cent), *i. e.* nitric and tartaric acids, prevent the light from exercising its usual transforming action. Oxalic acid has the property of accelerating and rendering more intense the change in the starch (as shown by the action of iodine) under the influence of light. Its action is comparatively *nil* in the shade.

Whatever it be, unique or primordial, primary or secondary, the cause of the changes described is light.

Dextrine is rather a product of art than of nature. Dextrine obtained by diastase does not reduce Bareswill and Fehling's reagent, and undergoes no transforming action from solar light. None of the bodies studied appear to develop this influence. Yet these same bodies, without light but with the presence of heat, are suitable to profoundly modify this same dextrine, as much as ordinary heat differs from solar light in its effects upon organic bodies.

Cane-sugar undergoes no transformation from the action of solar light: substances like hydrochloric acid and nitric acid, which modify it profoundly, act as well in the dark as in the light. Nitrate of uranium effects no more change upon it in the light than in the dark.

With concentrated sulphuric acid it requires a boiling temperature to decompose oxalic acid, one of the educts of starch: without concentrated sulphuric acid, it requires a temperature of 248° F. to 375° F. to disengage the oxide of carbon. Oxalic acid diluted to one twenty-fifth, in presence of nitrate of uranium one per cent, boiled or kept in a stove for forty hours at a temperature of 104° F. does not disengage a bubble of gas, if it is kept in the dark.

When it is exposed to the light, even diffused, upon raising the cover of the stove, the mixture remaining at 60° F. or 68° F., the decomposition begins. An hour's good solarisation furnishes an abundance of inflammable carbonic oxide gas.

Direct experiments show that animal fecula (glycogene) is transformed into sugar more rapidly and abundantly under the influence of light than in the dark. But nitrate of uranium hinders, not accelerates the solar influence upon animal fecula.

Animal fecula, like vegetable fecula, remains in the liver of frogs during winter without becoming sugar. The period of greatest richness of sugar in the liver of these animals exactly corresponds with the period of the maturity of fruits: the end of June, July and August. The glycogene may remain unaffected in the liver (like starch in the tubercules of grain): if the frogs are entirely protected from light then they produce no sugar.

We can now explain how the abundant presence of glycogene in the cutaneous tissue of the fœtus disappears from that tissue immediately after birth, by the sudden transition from darkness to light.

The actions of light sketched above are generally slow. We know also how this action of light, daily feeble, in time effects the formation of corn and the ripening of fruits, &c., nevertheless, it is powerful, as a whole. Therefore if, without augmenting the light,

certain substances double, treble, or sextuple the effects of the solar action—for example, in the formation of animal or vegetable sugar —and if, on the other, without diminishing the solar intensity, other substances annihilate or hinder its effects, as, for example, starch under the solar action—we cannot doubt that analytical studies in this direction must be very serviceable both to agriculture and to vegetable physiology, and perhaps even to medicine. It is only necessary to refer to the influence of solarisation upon scrofula and diabetes. We know very little, for instance, of the phenomena of nutrition. An experimentalist on these phenomena met with the following curious incident:—He took some starch saturated with iodine and placed it in his garden in a pot imperfectly covered with a piece of wood, where it remained for three months exposed to the sun. Upon opening the vase he was astonished to find in it some scores of snails attracted from all parts of the garden. Continuing the experiment, he saw during even the greatest heats of summer the snails daily travelling towards the pot. They were attracted by the iodine and not by the starch. He is of opinion that if a quantity of sawdust be saturated with a weak solution of iodine, it might be made the means of attracting these pests of the garden to their own destruction. The process is not costly, as the iodine, notwithstanding its volatility, retains its efficacy for years. Snails and slugs are a popular remedy for consumptive patients, may it not be from the iodine that they, probably, eliminate from the soil and certain plants? J. P.

"AUDI ALTERAM PARTEM."

A FEW WORDS IN FAVOUR OF BRITISH ART AND ARTISTS.

To the Editor.

Sir,—Will you permit me to offer some few remarks in connection with the two last letters addressed to the Young Photographer, "Eusebius," who being pulled up so suddenly and unexpectedly when in the midst of a successful career in pursuit of a favourite art, to listen to a prosy lecture about a "sixth sense," and the present fallen and unhappy state of "British Art" and Artists, is, I am sure, a fit object for our sympathising pity.

I, sir, am a member, unfortunately, of that degenerate race "mostly slaves of convention," who worship the "golden calf, Art," and are called "artists;" but, alas! I must lay down the brush, relinquish my dear old palette, and turn with a sigh from the tempting canvas, for I have only five senses—only five!—and consequently cannot be an "artist born." It is certainly true that I don't know what this "sixth sense" is, or how its existence is demonstrated, as I innocently imagined that the cultivation of my mind generally, and the education of my imitative and perceptive organs more particularly, were the origin of the feelings which took possession of my heart when in the presence of nature's glowing beauties, and of the power I have acquired in expressing them.

With regard to the missing "bump" not "mapped down by phrenologists," and several times refered to as the "art faculty," a phrenologist would inform the writer of these letters, doubtless with a smile, that the perception of the beautiful is a perfectly distinct thing from its imitation, and that what he terms a "faculty for art" has its origin in the combined powers of certain organs or "bumps," called respectively ideality, imitation, form, and colour, aided by the reflective and perceptive faculties. Thus it is that many possessing certain of these qualities and wanting others "enjoy the beauties of nature" thoroughly, but cannot "utter what they feel, either by pen or pencil;" and others, copying nature with the fidelity of a machine, devoid of all feeling, yet arouse by their productions lofty sentiments and poetical feelings in others differently organised.

Is not this "letter writer" *rather* too bold, if, as he says, he "cannot arrogate to himself any special knowledge" to make the sweeping assertions, that *he* has generally found "art teachers to be blind leaders of the blind," and that "the British school of art in this middle (has it any other?) of the nineteenth century, has no better representatives to hold up to the admiration of posterity than the so-called pre-Raphaelites." I think there are some artists belonging to "this middle of the nineteenth century" *not pre-Raphaelites*, to whom "the admiration of posterity" will be very probably awarded, viz., Turner, Stanfield, Maclise, Landseer, Mulready, Creswick, Harding, Leslie, Frith, and others painters who as readily threw aside the eccentricities of morbid novelty as they did the glaring conventionalities which deface the pictures of that lover of attractive "shams" and idle method, *Gainsborough*—an artist who, with nature at his elbow, could compound a landscape with a little earth, bits of stick, some weeds, stones, and a piece of looking glass, and *paint from these*—many parts of whose pictures are about as true to nature as the conventionally antique and formally stiff outlines of *Flaxman* are to beauty.

In the last epistle I find it asserted that "nature is dumb and inert matter," and that (the golden calf) art clothes it in thoughts, and gives it a language. Nature *dumb!* Oh! Shakspeare! how mistaken you were in supposing there were "tongues in trees, books in the running brooks, and sermons in stones!"

In conclusion, I must just say something in favour of colour, which, without disparagement of its twin sisters, outline and relief, is by no means the least of the three.

We have many excellent draughtsmen, very few good colourists; this is a well known fact. Now how do we account for this, that colour, a picture's most popular and attractive quality—as witness the desperate attempt to supply cheap coloured prints, and the success which has rewarded the most feeble steps in that direction—should be in its comparative perfection the rarest acquirement of the most gifted artists? Is it because it is easiest or most difficult, most attractive or least attractive? I will give you what, if I mistake not, is the reason. The art student begins to draw, and from every quarter is assistance proffered. Here are minute and accurate measurements, treatises without end, systems innumerable, and whole libraries of books to assist him. Thus aided, and with moderate ability, he succeeds; outline and relief are mastered, and he turns eagerly to the crowning glory, the poetry of his art—*colour.* But now he looks in vain for aid: no figures, no clearly defined principles, no easily acquired systems wait his beck or come at his call; he is alone. Severe thought, indomitable perseverance, long and tedious practice—these are now the only roads to the goal of a successful colourist—a goal which most probably he never reaches. Well, you know the old fable of the fox and the grapes. Nothing is easier than to decry the merit we do not possess. The old Roman artists, who could draw grandly but coloured villanously, of course scorned colour, saying design and drawing (*their best qualities*) were everything, colour (*their worst*) nothing; that the latter was useless without the former, &c., in short, just what the master of "Eusebius" says in his last epistle.

In attempting to defend British art and modern artists from what I think injustice, I would not be understood to deny the ability displayed by the author of these letters in his reasoning and deducements relative to outline and *chiarooscuro*, but simply to express a contrary opinion relative to the present state of art in this country, as compared with the conventionalities displayed in the works of two examples so highly lauded in his letter, and to show why I think he has not been quite just to the important aid of colour. Some of this writer's remarks deserve high praise, but others aroused in me a warm feeling of indignation, under the impulse of which I confess that I write the present letter.

Apologising for the time I have occupied, I am, yours, &c.

AN ARTIST.

[Upon the principle of giving *both sides* of an argument a fair hearing, we usually insert anything which we receive questioning our own judgment: we can do no less with regard to that of one of our *collaborateurs.*—Ed.]

FADING OF NEGATIVES.

To the Editor.

Sir,—Whilst much has been written on the fading of paper pictures, I can find little or nothing on the fading of those on glass; yet in my experience I am sorry to say I have lost many choice ones, negative and positive, in that manner—indeed, nearly all that I have had any time are thus more or less spoiled. They become spotted and streaked, from the margins gradually over the whole plate, though sometimes stains appear in the centre first. The film likewise often cracks in several places, as if cut with a knife; and the varnish sometimes comes off as a fine powder.

I endeavour to take every care in the manipulation. The chemicals are of the best. The varnish is amber and chloroform, not applied until the plate is thoroughly dried. The hyposulphite is well washed off after fixing: in short, I cannot find any cause, unless it be a hygrometric state of the glass, which is always damp, though kept in a deal or walnut wood box, in a warm room. If I dry the back at any time, it becomes damp again very shortly, and this, I conceive, takes place on the other side as well, and thus affects the film.

It is very vexatious to lose one's best negatives in this way; and I shall feel much obliged by any explanation and remedy, and should like to know if others suffer in the same manner.—I am, yours, &c.

Bristol, September 16, 1859. MEDICUS.

[You have not mentioned what kind of glass you employ; but if, as you state, it becomes damp shortly after wiping in a warm room, it is quite unfit for photographic purposes. To say that we have *never* lost a negative by fading would be untrue, but when we have done so it has always arisen from *pure carelessness.* Exposure to damp, even when properly varnished, will affect them sooner or later.

Positives on glass are liable to deterioration in brilliancy, if not varnished, from noxious vapours; and if varnished, the varnish itself often degrades the tone.

We are almost tempted to fancy that your trouble may be due to the pyroxiline of which your collodion is made being insufficiently washed before use, or else improperly made. Have you tried varieties of collodion? —Ed.]

CHEAP CAMERAS FOR DEROGY'S LENSES.

To the Editor.

Sir,—As you have been kind enough to give photographers a clear account of what they may expect from the performance of Derogy's lenses, I am induced to ask if you could confer the additional favour of telling us how or where we can get cheap or serviceable cameras with sufficient focal range for the various combinations of these lenses. In addition to the usual collodion frames, they should (I think) have double paper slides for the larger-sized pictures.

M. Derogy's price list says nothing on the subject, and the ordinary cameras of the shops are of no use in this case, while a suitable camera, capable of taking large and small pictures, made to order, would probably be so costly as in great measure to deprive amateurs of the benefit to be derived from a good cheap lens for large pictures.

I am, Sir, yours, &c. ?

[The cheapest cameras with which we are acquainted are the French walnut-wood ones, costing about 35s. to 40s. for what they call a whole plate size: these answer very well for portraits, but having a tail-board, and being heavy, they are not so well adapted for landscape purposes.

We no not think it politic to endeavour to make the same camera answer for portraits and landscapes, as in using it for either purpose you must always bear some inconveniences, in consequence of its adaptation for the other. In having two or more cameras it is a good plan to make the plate frames fit them all, and also to have sliding fronts removable and fitting each of the cameras.

We shall be glad of suggestions to solve the problem propounded by our correspondent. Our own notion lies in favour of cameras made of yellow pine, well oiled with boiled linseed oil and varnished. We want however some cheaper and more easily made plate frame than now exists to work with the above. Some short time back Mr. Hughes suggested vulcanite for this purpose, and we consider the idea a very happy one, as if made in quantities they could probably in this material be produced at a moderate price. We shall possibly give a further hint or two in our next.—Ed.]

PRACTICAL DETAILS.

To the Editor.

Sir,—I constantly notice in your interesting Journal answers and questions which I dare say to you are in a great measure foolish, therefore I am emboldened to propose some of the same description. I should still hesitate but that I know you are always willing to help those who are in difficulties. I shall be extremely obliged by your answering any or all of my propositions, and shall, with your numerous engagements, consider myself not hardly dealt with if you take no notice of this communication.

1. Is it necessary for developing solutions to use pure alcohol, or will good naphtha or methylated spirits do?

2. Would you be kind enough to give me a good formula for negative developing mixture?

3. Is it best to develop with iron and then strengthen with pyrogallic acid, before or after fixing with cyanide; or is it advisable to complete the whole with pyrogallic acid at one operation?

4. For a portrait background in the open air, what colour is the best?

5. For landscape stereoscopic work is it desirable to have one or two lenses?

6. Will twin portrait lenses answer equally well for view work, when one glass from each lens is removed and a diaphragm inserted?

Your kind attention will oblige.—Yours, &c.

Liverpool, September 26th, 1859. VERY GREEN.

[1. It would not do to use wood naphtha, and methylated spirits are decidedly objectionable in a proportionate degree. It is bad economy to use any but the pure alcohol, though it is not necessary to be of very great strength.

2. *a.* Pyrogallic acid one grain, distilled water six-and-a-half drachms, Beaufoy's acetic acid one-and-a-half drachms; or, *b.* pyrogallic acid one grain, distilled water seven-and-a-half drachms, glacial acetic acid half a drachm; or, *c.* pyrogallic acid one-and-a-half grains, distilled water seven drachms, citric acid one grain, alcohol one drachm.

3. In *cold weather* develop with iron, clear with cyanide, and strengthen with pyrogallic solution. In hot weather the iron is not necessary—in moderate weather do as you like.

4. For a light ground, a blanket; for a dark one, a piece of red baize; or grey for medium.

5. Two decidedly.

6. No.—Ed.]

THE ARCHITECTURAL LENS.—INSERTION OF PHOTOGRAPHS IN TOMBSTONES.

To the Editor.

Sir,—In reply to "T. S.," who writes privately, wishing to know if the defining quality of Sutton's triplet is as good—size of stop considered—as that of the Petzval combination, and if it answers as well for general landscapes as this latter, I would remark, that while the Sutton lens which we (the testing committee) submitted to trial gave absolute straightness of lines, it required a very much smaller stop than any of the others to get definition. This may have arisen from some slight imperfection in the individual lens tried, which I think was one of the earliest made; and without seeing some more "triplets," I would not venture to assert that, in definition, this is not equal to the Petzval form. Further experience in their manufacture may eventually lead to the attainment of good definition with as large a stop as that required by others; but in the meantime the very small stop required will be a bar to its popularity, except for architectural purposes. The want of definition in the triplet which we tried may perhaps be accounted for in the fact of the front lens having been a non-achromatic meniscus of crown, the correction of which would be effected by the biconcave centre lens of flint. Mr. Sutton, I think, recommends the front lens to be achromatic as well as the back one, and the small central concave to be of rock crystal.

With respect to the "New Use for Photography," at page 226 in your last number, I am really sorry to have to displace the laurels from the brow of Mr. Murray, but in justice to Edinburgh it must be stated that photography has been applied here for some time past in the way he suggests. It is at least a year since Mr. Tunny erected, in Warriston Cemetery, a handsome monument at the grave of his wife, in which is inserted a photograph on porcelain. This has been seen by thousands.—Yours, &c. J. T. TAYLOR.

81, *South Bridge, Edinburgh.*

[We do not think that a lens constructed as described would do justice to the principle upon which it is founded.

Opticians have an objection, based upon experience, to transmitting an *uncorrected* ray for any distance; were it not for this circumstance the two meniscus lenses might just as well be made of simple crown glass, and be *both* corrected by a simple biconcave of flint glass between them.

The term "triplet" is not usually applied to such combinations as the above named; but generally indicates a compound lens of three pieces with the continguous surfaces in contact.—Ed.]

THE POSITION OF THE DIAPHRAGM.

To the Editor.

Sir,—May I beg the favour of a reply to the following query in the forthcoming number of The Photographic Journal?

Which is the proper position for a diaphragm or stop in a double combination lens when used for landscapes or groups—midway between the anterior and posterior combinations, or immediately before the anterior?

Opinions are so divided on the subject, I greatly wish to have the weight of your authority to settle the question.—I am, yours, &c.

GEORGE HAYDON.

Eccles, September 23rd, 1856.

[For landscapes, the diaphragm to a double combination lens should be unquestionably *between* the components—not quite midway, but rather nearer to the front lens, that having usually the shorter focus of the two.

By this arrangement the illumination is rendered more even and the distortion of marginal line obviated.

Why not try for yourself? Glue together two or three thicknesses of brown paper, and cut out diaphragms to suit each place, and take pictures under both circumstances. With the diaphragm between the lenses you will find a *larger field* is covered than with the same in contact with the anterior portion.—Ed.]

ANSWERS TO CORRESPONDENTS.

Samuel. R.—The first on your list.

Pax.—Never too late to mend: try more acetic acid.

Thos. Gulliver.—We shall be happy to receive the communications named.

Purblind.—If you cannot clearly *see* your way, resort to *feeling*, and hand out the subscription solicited to the Archer fund at once.

C. Prettyman.—You will find a full description of our *orthographic camera* in a recent number of the Journal, published 15th June last.

M. S. D.—*Ten* grains of chloride of *ammonium* will produce as much effect as *twenty grains* of chloride of *barium*, consequently your experiment proves nothing relative to the point you aimed at.

Subscriber (Colchester).—In our last, a portion of our reply to you was inadvertently separated from the rest by the printer in "making up" the form, he having mistaken the word *rationale* for the pseudonym of another correspondent.

Geo. K.—We have seen the article for which you ask advertised lately for sale—we believe by J. Solomon, Red Lion Square, London. You may very likely be able to make some that will answer well enough by coating paper with Bates's black varnish.

Amateur. Henry Robertson. B. L. Ignotus.—We let "the other side" speak this time—besides, we have *no room* to do as you request in the present number, even if we had the time. We shall probably do so in our next—but at any rate in an early number.

Received.—"D. L."—"C. J. B."—"Ak.",

THE PHOTOGRAPHIC JOURNAL.

No. 104, Vol. VI.—OCTOBER 15, 1859.

In our last we were enabled to lay before our readers a tolerably elaborate account of the proceedings and the various papers connected with the art of photography that were read at the recent meeting of the British Association for the Advancement of Science at Aberdeen. The great length to which our report extended, and the near approach to the time of publication before we got the whole before us precluded the possibility of our making many comments on the subjects brought under notice. We therefore propose to touch upon some of them on the present occasion.

First in importance *to photographers* appears to be the "Report" by Professor Maskelyne, and Messrs. Llewellyn, Hardwich, and Hadow, *On the Constitution of the Photographic Image;* and we think it but fair to remark that we were only enabled to obtain, in time for our last, a reporter's *abstract* of the paper, consequently that many of the most important data upon which the conclusions arrived at were formed are not as yet before us. It would perhaps be impossible to select men better qualified to undertake the requisite investigations than the gentlemen who are responsible for the report; we are, therefore willing at once to conclude that they have very strong grounds for the opinions they have expressed, although they differ *in toto* from those of the eminent French savans who have employed themselves with a similar inquiry. We have before now expressed our dissent from some of the views put forth by the latter, but we are certainly somewhat surprised at those of our own countrymen—not because we have any reason to question their soundness, but inasmuch as they are somewhat unexpected. We shall look forward with considerable interest to an opportunity of studying the paper *in extenso.*

One point of marked disagreement with the conclusions of our continental brethren will be found in the view taken relative to the first action of light reducing the argentiferous compound to a state of sub-oxide—an idea which our foreign friends strenuously oppose.

We cannot help fancying that there must be some mistake in the report of the observations of the President of the Chemical Section after the reading of the paper just noticed. He is quoted as having remarked as follows, viz.:—

> "If you take any calotype and dip it into a solution of bichloride of mercury it becomes perfectly white, *and no vestige of the image remains;* but afterwards, if it be placed in hyposulphite of soda, it becomes completely restored. The mode in which the chloride of mercury acts in rendering the image latent has, as yet, as far as I am aware, received no satisfactory development" (explanation?).

We certainly were not aware that any *mystery* connected with this simple matter existed. The explanation appears to us clear enough. In the first place, the image after the action of the perchloride of mercury is *not latent,* and only invisible when the paper upon which it rests is perfectly white and colourless; and in the second, it is not only by the action of hydrosulphate of soda that the image may again be made apparent; hydrosulphate of ammonia, hyposulphite of soda, liquid ammonia, &c., or any analagous agents, can be employed to reinstate the image.

The explanation is this:—the bichloride of mercury is decomposed, one atom of chlorine uniting with the silver of the image, causes a deposit of proto-chloride of mercury (calomel) in the form of a white powder, to be formed, with an intensity exactly proportionate to the amount of silver previously there. The image is therefore accurately depicted in *white,* and, if the supporting layer were black, would appear as a negative. On the addition of a compound containing sulphur, the mercury becomes released from the chlorine, and uniting with the sulphur forms a dark brown sulphide of mercury, and consequently upon a white ground the image again becomes visible. In a similar manner the action of ammonia gives rise to the production of protoxide of mercury of a black colour, and of course in this case also the image is restored to the eye. There may be something more mysterious than we have stated above, and if so, we shall be obliged to any one who will kindly indicate in what it consists.

Some specimens exhibited by Dr. Gladstone, illustrative of the actinic inactivity of light reflected from fluorescent substances, are highly interesting, as in part explaining why *colours alone* are not to be taken as a criterion of the probable amount of actinic influence of which the light reflected therefrom may be possessed. This is a subject of peculiar interest to us, and one to which we drew attention formally about fifteen months ago, as may be verified on reference to our last volume, pages 174 and 175, in a paper entitled "Suggestions relative to testing qualities of glass intended for Photographic Operating Rooms," and casually on several previons occasions. If we remember correctly, also, an illustration of a similar matter was exhibited not long since at a meeting of the Blackheath Photographic Society, where slabs of porcelain, tinted of various hues by metallic oxides, &c., and similar hues by different agents exhibited, on being photographed, the fact that colour alone could not be relied on for predicting the result.

The experiments of Dr. Gladstone are striking, and certainly suggest the probability of a satisfactory explanation of the phenomena. It must not, however, yet be recognised as *un fait accompli,* until those coloured surfaces which are inactive in reflecting the chemical rays have been extensively examined, and pretty generally found to possess more or less the quality of fluorescence.

There is one fact that occurs to us at the moment of writing which appears to militate against the phenomenon of fluorescence being of itself sufficient in all cases to account for the want of actinic energy, and this is, that in copying a painting in many colours the effect produced in the photograph differs materially according to the inclination of incidence of the illuminating rays—a fact which would seem to point to *polarisation of the light,* as also influencing the result; and, furthermore, the character of the light employed also affects it.

We really cannot help feeling sorry at having to throw even the shadow of a doubt upon the satisfactory nature of the fluorescent theoretical explanation, it seems so perfect; and, as Dr. Wilson observed, "If we acknowledge the fundamental principle of the co-relation of forces, then we cannot expect to change an invisible chemical ray into a ray of light, and retain the same chemical power." The force of this observation applies, in all its integrity, to the photographic phenomena influenced by fluorescence, even if it should eventually appear that fluorescence

alone is not sufficient to account for all cases in which the variation of effect from colours alike to the eye occur. Here is a wide field of usefulness open to any zealous photographer in search of a direction in which to expend his energy.

Perhaps the most generally interesting paper of all that were read at the late British Association Meeting upon photographic matters, in a popular point of view, was that of Mr. Warren De la Rue *On Celestial Photography.* We say popular, not because it was any the less scientific than the others — as we regret to say is the case with most attempts to render science popular — but because it is one in which everybody can feel an interest, whether photographers or not. Some of the most striking facts to which our attention has been directed in this paper are:— the much greater difficulty experienced by the delineator of celestial objects than falls to the lot of one who operates only upon those terrestrial; the ingenious arrangement proposed to vary the rate of motion of the clock movement to the telescope at will, viz. — the introduction of the disc and plate motion; and a fact that we regard as of considerable importance to photographers, the much smaller loss of actinic power by reflection than we should be led to anticipate from a knowledge of the amount of deterioration of the visible rays. This should not be lost sight of, as it may be useful to remember when contriving certain pieces of apparatus hereafter. That the full moon should be capable of impressing its image photographically more rapidly than when in part illuminated, might of course be anticipated by any one who considers the subject, because in the latter case the solar rays fall upon the satellite obliquely to the spectator, instead of perpendicularly, as in the former; but how few of us are likely to have thought about it until we had tried the experiment and wanted an explanation for the phenomenon observed!

Lastly the description of the photo-heliograph employed at the Kew Observatory for recording, by means of photography, the appearance of the sun's disc and the progress of the spots across it, will no doubt have been of interest to every reader.

We are desirous of correcting a slight error into which we had fallen relative to the late Mr. Andrew Ross, whom we stated in our obituary to have received the Gold Isis Medal and the sum of fifty guineas from the Society of Arts, for the *microscope* made by him for Mr. Valentine, and from that gentleman's design. We find that it was for the *Dividing Engine* that Mr. Ross received the above-named prize, and that Mr. Valentine himself received the silver medal for the design of the microscope. While on this subject, we may also mention that the late Mr. Ross was educated at the Bluecoat School, and that before setting up in business on his own account as an optician, he worked for two years in the shop of an engineer; and he used to affirm that he acquired more information there relative to practical mechanics than he could ever have obtained amongst the opticians.

PHOTOGRAPHIC CONTRIBUTIONS TO ART.

It is with no small amount of pleasure that we have felt called upon to notice from time to time, under the above heading, some very meritorious productions of photographic skill. Every week now furnishes fresh evidence of the important aid afforded by it towards the development of art, and we will cite one or two instances that have recently come under observation.

In the Suffolk Street Gallery there was exhibited a painting called *The Mother's Hope.* It was not difficult to see that the artist had been "ploughing with another man's heifer." It may perhaps be borne in mind that a series of groups, illustrative of *The Seven Ages*, by Mr. Rejlander, was exhibited in the last collection of the Photographic Society (in the same locality by the way), one of the groups being, "*The infant mewling and puking in the nurse's arms,*" a group which, if we remember rightly, was laid under heavy condemnation by a bashful critic, upon the ground of its having offended the sense of propriety of a prudish old maid at the *soirée* held in the exhibition room. Now "The Mother's Hope" is drawn precisely after the model of this group; the general arrangement, the baby in the lap, &c., all being exactly the same, the chief variation consisting in the infant smiling instead of playing the part that Shakspeare had set down for him.

Would any of our readers like to have ocular demonstration, let them procure a copy of the *Illustrated London News* for the 27th August last, and they will find therein a woodcut taken from the painting.

We are not asserting that the application of the idea is not legitimate, any more than if the artist had seen the group in nature and reproduced it; but we do assert emphatically that it is a convincing proof of the valuable aid that artists may derive from photography, and we must put in a claim for a small share of the credit being justly due to Mr. Rejlander.

While on this subject we may remark, *en passant*, that the attempted reproduction by woodcuts are not always so happy as in the present instance; witness the awful caricature of Mr. Robinson's *Fading Away* which was perpetrated some time back without the consent or knowledge of the artist.

We have also heard of another painting having been sold early in the present year, which was *copied altogether* from one of Mr. Rejlander's photographs, being *a Gamekeeper and a Peasant*, with basket and other accessories.

These facts speak for themselves, and Mr. Rejlander, like a sensible man as he is, instead of grumbling at being made useful to others without his permission being first obtained, has turned his attention to the means of affording a supply of his compositions at a very cheap rate, while still maintaining their original excellence. In order to accomplish this object he has been making experiments in copying his original compositions by means of his Petzval lens, and with such success that few, if any, would find out that they were copies at all, as they possess all the roundness and brilliancy of the originals.

There are many, very many, who would be delighted to possess a good specimen of the first proof from many negatives exhibited by this artist — the *Two Ways of Life* — but who are unable to afford the luxury of a large proof, while the smaller copies as heretofore produced, though possessing all the same grouping and outline, were far below the larger ones in brilliancy. Now, however, they may freely indulge their desire, for Mr. Rejlander has succeeded in producing from his *best original* a minature negative retaining all the beauty and exhibiting none of the grain of the paper. The result is truly beautiful, and we strongly advise all lovers of our art to send for a copy, which will cost but a trifle, and well satisfy them.

The Wayfarer and *God Speed Him* have been treated in like manner, and should the public appreciate the efforts thus made to meet their wants, no doubt other compositions will be forthcoming also.

PHOTOGRAPHERS THEIR OWN ARTIFICERS.
No. 1. PORTABLE TENT.

By Thomas Gulliver.

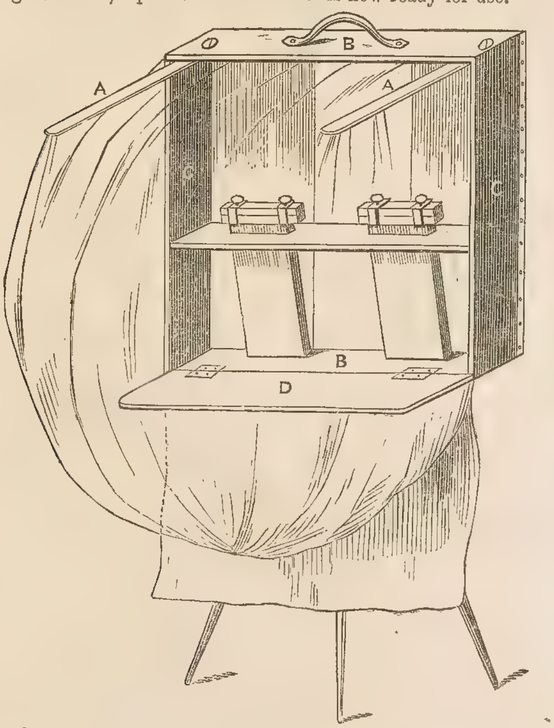
Enclosed I send a sketch of a portable tent that has proved to me a real treasure in working the wet collodion process in the open air. I formerly worked with a tent fitting over the camera stand, and have tried a host of developing boxes, and lost much money, time, and temper, in constructing and trying to work these uncertain contrivances. Photographic barrows and carriages may be well enough in some places, but not very well suited to take into a railway carriage, or over steep hills and through valleys, where sometimes the wandering photographer is bound to go. My tent is not more cumbersome or unsightly than a carpet-bag, and the weight a mere trifle. Any one can make it with little trouble or cost. The following is all that is wanted for it:—

A	2 pieces of ash,		$18\frac{1}{2} \times 1 \times \frac{3}{4}$ inches.	
B	2 pieces of yellow pine wood,		21×5 inches.	
C	2 ditto	ditto	$19\frac{1}{2} \times 5$	"
	2 ditto	ditto	21×5	"
D	1 piece ditto	ditto	$19\frac{1}{2} \times 6$	"

3 screws and nuts, a few strips of red leather, and some brass tacks.

6 yards black casban or silesia,* and 4 or 5 of yellow calico.

A square frame is to be made first, 20 × 19 × 5 inches. A shelf is then fixed across, to support the nitrate bath and the washing bath. An upright is then to be affixed, not quite in centre, to keep the frame firm. A shelf is now united to the frame with hinges, so as to fall down, and with the bottom of the box form a small table to develop on. The frame is now complete, and must be covered in front with the black casban (double), having a strip of yellow calico, four plys thick, sewn down the centre for a window. The rest of the black and yellow material is now formed into a sort of bag, which is tied round the operator's waist; and the apron in front being tucked in, a perfect dark chamber is now ready for use.



In fastening the black casban round the frame-work, it will be best to strain it over the edge of the wood-work, and then tack it neatly to, using the strips of red leather and brass tacks. The wood-work must be brushed over twice with a varnish, composed of

Shellac	2 ounces.
Wood naphtha	6 "

Mix and dissolve.

This will give it a nice appearance, and with the red leather binding and brass nails, it will be such a parcel as few will object to carry. The fittings required inside are a gutta percha bath for silver solution, with tight top, a wooden washing bath, also with tight top, two 2oz. bottles for collodion, two 4oz. bottles for developer, a developing tray, two plate boxes, and small sponge. The manipulation will slightly differ from the usual mode in order to suit the internal arrangements of the tent that I propose to explain in your next number, and to give directions for making deal cameras, camera stands, plate boxes, dark slide, developing trays, water-tight top washing bath, dippers, &c. All the above have stood the trial of the heat of last summer, and are now as good as ever if varnished over with the shellac varnish. The changes of weather do not affect them, and the saving of weight and cost is considerable. With the tent I started yesterday to photograph Oystemouth Church, "about to be rebuilt;" arrived there by two o'clock, and left by half-past four o'clock, with five negatives, three whole plates, two stereos, out of six glasses taken. Prints from one or two I will send next week, also a photograph of the tent. The deal camera I am now using weighs no more than two double dark slides of old make.

* Used for backs of waistcoats.

THE SOLAR CAMERA.

In order that our antagonists upon the question raised relative to the alleged novelty of the above-named instrument might have the utmost advantage for stating their own case, we abstained in our last issue from entering as fully into it as we had intended on our side of the argument; but as we find from correspondence that there are some of our readers who desire further information, we now purpose continuing the discussion. On reference to our article in No. 102, p. 223, we perceive that we inadvertently omitted to state the fact that, although we inspected Mr. Wenham's specimens privately at first, *they were publicly exhibited to the members present at the Meeting of the Photographic Society held on the 1st December*, 1853, when his paper was read; and, as the meeting was well attended, there are plenty of individuals enabled to give evidence of the fact, if there be those who are inclined to question the accuracy of our memory.

In order to let our readers know what is thought about the matter in America, we extract *verbatim* the following from the 1st September No. of a respectable periodical, *The American Journal of Photography,* reputed to be the organ of the National Photographical Society. It will be perceived that the editor does not regard us personally with favour, consequently we presume that his testimony will not be deemed partial:—

"EDITORIAL MISCELLANY.

——— "The subject of the latest nine days wonder among our foreign cotemporaries is the 'American Solar Camera.' At last our friends confess that they owe something to American genius; they have fed their eyes with the vision of a solar camera—a genuine article, all the way from America—they have imposed their hands on the machine. Eureka, cries each one, and ruthlessly assaults the dictionary for adjectives to express his laudations. Mr. Sutton expects a photographic millenium; M. l'Abbé Moigno, who in the beginning of a long article in *Cosmos* of July 22nd, boasts:—'We are certainly the first to call attention' to the solar camera, declares that the great invention has been made 'providentially' for the glory and advancement of photography.

"And in the loud chorus of praise the only notes of discord come from the Liverpool Journal. Mr. Shadbolt promising to examine the apparatus says, 'We are not sanguine about finding any novelty much less ground for a patent.' But it must be remembered that Mr. Shadbolt is notoriously severe on American affairs, delighting to print even vulgar blackguard if directed against American photography.

"Mr. Woodward, of Baltimore (our neighbours call him 'professor'), is making a photographic tour in Europe with his camera and specimens. We are not personally acquainted with Mr. Woodward; we never considered the solar camera a great or useful invention, but we are persuaded that Mr. Woodward has elements of greatness; else how could he throw dust so accurately that our English friends were blinded to the fact that *six years ago they used the same apparatus,* and that our French friends were oblivious of the fact that Chevallier has for years manufactured and figured in his catalogue and other publications the *camera solaire,* and claiming to have first constructed it in 1839; and the probable fact that the first life-size photographic portraits were made in Paris by the American Thompson. Also Mr. Woodward made our foreign editorial brethren forget that a year ago, and more, they had read in the American Journal of Photography, the mathematical principles to be observed in enlarging photographs, and a demonstration of the imperfections of Woodward's contrivance, and a description from New York papers of a photographic portrait on a scale of Twenty-Five feet correctly enlarged, and by a better intrument than the solar camera. Perhaps, indeed, at that time our foreign brethren looked with such contempt on American photographic literature, that they did not humble themselves to read what was written on the subject. Mr. Woodward deserves well of his country; he has elevated the American Eagle; we will welcome him back with outstretched arms; we will compliment him with a banquet and medal.

"But in veriest seriousness, does not the grand triumph of solar camera in Europe seem like an unsubstantial vision to our readers who understand the enlarging process.

"We venture for ourself an explanation of the whole phenomenon, which an examination of almost any foreign journal will illustrate. These journals advertise as a habit and custom, not only in their advertising columns, but editorially, what we should here call quackery. They publish constantly letters from photographic dealers and pseudo inventors puffing what they have for sale. Such practices and such habits are certainly not conducive to fair scientific criticism; what better illustration of the effect of them can we have, than the recent glorifications of Pouncy and Niepce de St. Victor? While our neighbours sneer at what they imagine the peculiar American character, let them look at home for examples of the *Yankee.* At any rate there are so many subjects abroad for a *cute* practitioner, that if we felt inclined to encourage such genius as that of the Rev. Hill, and of the inventors of collodion gilding, we should prescribe emigration.

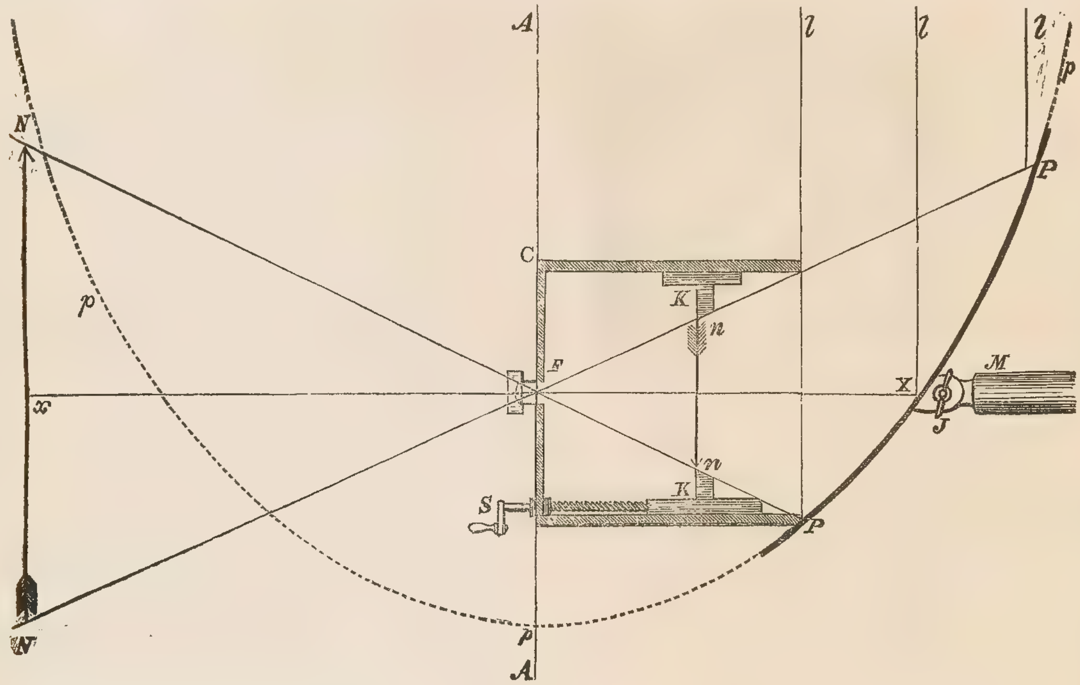
"We observe that Mr. Woodward talks about the ammonio-nitrate process in connection with solar camera. We are not aware that any of our American

sunlight has been exported to penetrate the fogs of London. Perhaps some of the purchasers of the solar camera may be induced to send for the New York *Sun*; it costs only one cent. per day, it might prove useful in an unenlightened quarter."

As our immediate object is to discuss the matter of producing enlarged proofs from small negatives, we shall not attempt *at present* to correct the false impressions of our American contemporary relative to the sentiments that he imagines us to entertain towards him; perhaps we may do so at some future time, unless indeed, what is not at all improbable, he may find out his mistake when he knows us better. We proceed therefore to explain more fully the views advanced in our former article.

Of course it is obvious that in order to obtain the maximum of effect with a minimum duration of exposure, the direct solar rays must be employed, but in bright weather, when time of exposure is not so important, we are of opinion that we might consequently employ the diffused light of day; but in order to do so we must of course avail ourselves of converging rays, and to this end we conceive that it is preferable to effect convergence by means of a concave mirror than by a lens, thus avoiding dispersion. But this is not all, for as the sun is constantly shifting its relative position, when we desire to employ its direct rays a reflector of some kind is absolutely necessary in order to avoid the inconvenience of having perpetually to shift the whole apparatus. The amount of light lost by reflection from any given area of surface, whether curved or plain, would be the same in both cases, consequently by the use of a concave reflector we obtain convergence of the rays with a direct saving of the amount of light that would otherwise be lost by reflection at both surfaces of the lens, and also by absorption in consequence of the great thickness of glass.

We have before stated that the best form of curvature to adopt would be that of a portion of paraboloid of revolution, as it is the property of such a surface to reflect parallel rays falling in the direction of the axis of revolution to a point; but inasmuch as the lens employed for effecting the enlargement of the image will only transmit a pencil of light of limited angular aperture, it is of no use to apply to our apparatus a much larger surface of the paraboloid than may be included in the segment defined by such angle having its apex in the focus of the paraboloid. This will be better understood on reference to the following diagram:—



Let the plain and dotted line $p\ P\ P\ p\ p$ represent a parabola having its axis at $A\ A$ and focus at F. All rays falling parallel to A, the axis of revolution of the paraboloid will meet accurately at the point F.

Let C represent the segment of our enlarging camera having the lens (an orthographic one by preference) situated at F, and being quite open at the back. The length of the camera should be rather more than double the solar focal length of the lens F. At $K\ K$ is a sliding plate frame, having an opening in the middle, and capable of receiving square inner frames to hold the negative $n\ n$. This piece $K\ K$ should be adjustable towards and from the lens, and may be moved by means of a screw and crank handle S.

Now if $P\ F\ P$ be the angular aperture of the lens, the portion of the paraboloid cut by the revolution of this angle about its axis $X\ x$ would be all that is requisite for our purpose, we may therefore take a little latitude in all directions, and content ourselves with the portion indicated by the thick line $P\ P$, which will consequently *represent our mirror*, and it is manifest that the greater the distance between the points F and X the larger the surface would be from which light would be reflected, and therefore the action would be more rapid, as all the rays between those marked $l\ l\ l$ in the diagram would be brought into effective service, and these would increase in number with the area of the mirror.

If solely intended for use with diffused light, the mirror might possibly be advantageously made with a spherical surface, as by a proper adjustment the light could be collected from a larger area of the heavens, though not so accurately brought to a focus as parallel rays from a parabolic surface, and though this would probably be to some extent objectionable with direct solar rays, we do not think it would materially deteriorate the result when diffused light alone should be made use of, and in this case we are of opinion that ordinary salted albumenised paper might be exposed until a faint visible impression were obtained and then further developed by gallic acid.

For printing by the direct sunlight the camera should be placed with its axis $x\ X$ pointing towards the pole star, and the mirror mounted on a centre M, around which it should be made to revolve, the sun's rays might then be collected and thrown on the point F (thus passing through the negative $n\ n$) from sunrise to sunset, without requiring any alteration in the position of the camera. In order to meet the case of the variation of obliquity in the sun's inclination between summer and winter, a cradle joint at J would admit of the necessary adjustment, which would only require to be altered, and that very slightly, about once a week. It is true that this would in a trifling degree interfere with the rigid accuracy of the convergence of the rays to an exact focus, but not enough to make any practical difference.

Of course we need hardly mention that the paper to be impressed would be located at $N\ N$, or any greater or less proportionate distance from the lens according to the desired degree of enlargement.

As regards the mirror, we do not see any reason why even a spherical surface should not afford results equal in every respect to those obtainable with a plane mirror and condensing lens, with even greater rapidity, for reasons previously given. Concave mirrors of this description are neither expensive nor difficult to be procured: there might, however, be some trouble in obtaining them of the paraboloid form if it were requisite to have this *very* accurate; but we apprehend that sufficient correctness for this purpose would be arrived at by a skilful glass-blower with very little labour, and the silvering could be performed readily enough by the use of solution of nitrate of silver and oil of cloves or honey — a mode of working in common use.

In conclusion, we may remark that in selecting the Petzval lens in preference to any other kind, we do so because we believe it to be the best for rendering a correct representation of a plane surface upon one of a like kind.

M. DE LA BLANCHERE ON COLLODION.

In order to prepare a photographic collodion that will meet all the conditions required under various circumstances, it is first necessary to prepare various sensitising solutions. These solutions are composed of alcohol, holding in solution alkaline or metallic salts, which by double decomposition yield sensitive salts of silver, which, included in the layer of collodion, receive the impression of the rays of light. As the sensitive salts of silver are formed in the bath of nitrate of silver, we shall now premise that the base or metal we put into the photographic collodion will be left in that bath, increasing in quantity with the number of plates immersed in it, and removing an increasing quantity of silver. We can at once perceive how variable the composition of the silver bath must be, and how necessary it is to keep it always in good condition. Further experience will doubtless prove that most failures arise from defects in the silver bath.

All the sensitising solutions of which we give the formulæ improve by keeping, they should therefore be mixed before they are wanted for use; we are satisfied that the longer they are kept the more they increase the sensitiveness of the collodion to which they are added.

It is a very remarkable fact that the proportions of the iodides and bromides, and of the sensitising salts generally, greatly influence the quality of the negative. We require two opposite qualities in a portrait, detail and relief, and it is by sacrificing a portion of the first that we obtain the second. Now we can obtain the desired effect by a suitable sensitising of the collodion, as well as by an appropriate lighting of the object and careful focussing.

The salts of cadmium appear to be preferable to all others for sensitising, because comparative experiments have proved to me that, while it gives a rapidity more than sufficient and quite equal to that of other similar salts, it is more stable than any other. This stability in connection with the variable and uncertain elements of pyroxiline dissolved in alcholic ether is of the highest value, as it prevents the loss of old collodion, and also admits of the sensitised collodion being allowed to repose a sufficient time without fear of its altering in quality. For it is certain that this collodion is much more sensitive two or three days after it is sensitised than on the first day, which is not the case when an iodide of potassium or ammonium is employed, as they begin to decompose immediately they are mixed.

I also prefer the salts of cadmium, because their composition renders their integrity more certain; for iodide of potassium and ammonium vary to a considerable extent, in proportion as their porosity retains more or less of the interposed material. The pearly scales of iodide of cadmium are dry, uniform, and retain no foreign matter.

SENSITISING SOLUTION, NO. I.

Quick: great detail: deep shadows: yielding a perfect negative.

Iodide of cadmium	7.50 drachms.
Bromide of cadmium	1.25 „
Chloride of cadmium	0.25 „
Alcohol, sp. gr. 0.827	100 fluid drachms.

In this solution the proportion of sensitising salts is 9 per cent.

SENSITISNG SOLUTION, NO. II.

Very quick: much detail: good shadows: negatives less harmonious.

Iodide of cadmium	6.00 drachms.
Bromide of cadmium	1.00 „
Chloride of cadmium	0.25 „
Alcohol, sp. gr. 0.827	100 fluid drachms.

In this solution the proportion of sensitising salts is 7.25 per cent.

SENSITISING SOLUTION, NO. III.

Less detail: general effect, mellower but softer: not quite so quick: proofs more harmonious and artistic.

Iodide of cadmium	5.50 drachms.
Bromide of cadmium	2.50 „
Chloride of cadmium	1.00 „
Alcohol, sp. gr. 0.827	100 fluid drachms.

In this solution the proportion of sensitising salts is 9 per cent.

According to the quality of the alcohol employed, there will be more or less difficulty in dissolving the bromide and chloride of cadmium in the formula No. 3. These salts, much less soluble in alcohol than the iodide, often require several days for their solution. The bottle must be shaken frequently, and the salts pulverised in a glass mortar with great care.

All the above solutions are added in the same proportions to the normal collodion.

To prepare photographic collodion put into a graduated glass measure —

Collodion (thick or pharmaceutical)	100 parts.
Sulphuric ether, sp. gr. 0.735	100 „
Sensitising solution	20 to 25 „

This last dosage gives for each of the formulæ: —

No. 1. Sensitising salts	1.12 or 0.99 per 100.	
2. „	0.94 „ 0.83 „	
3. „	1.12 „ 0.99 „	

But the first will almost always suffice: we begin therefore by employing it, ready to add more, if it be not sufficient. Some sensitising salts, of different manufacture, appear to have more power than others to iodise a collodion.

The proportion of ether indicated above may be considered as a mean adapted for ordinary temperatures, 55° F. to 70° F. Above this temperature the quantity may be increased, and diminished if below it; but the quantity must not vary more than within one-third of the ether added, or 20 parts. It is, however, much better not to vary the original quantity, but to accelerate or retard the pouring on the collodion to the glass plate. If, however, the plate be very large, there is no alternative but to modify the collodion according to temperature.

Beginners should especially avoid changing their formulæ, for the less they vary the sooner they will succeed. The misfortune is that few are satisfied to let well alone, but hanker after something better, which can only be arrived at by great expenditure of time, labour, and patience, and if they fail in success, they rail at the difficulties of photography. Adopt a well-tried formula, and if you obtain good results, be satisfied with it; if you do not, attribute it to your want of care and perseverance, and try till you do succeed. — *La Lumière.*

ON THE PREPARATION OF GUN-COTTON.

By M. Van Monckhoven.

If ordinary pyroxyline be placed in a glass tube or retort, and submitted to the prolonged action of ammoniacal gas, a portion of the nitric acid passes to the state of nitrate of ammonia, the pyroxyline acquires a yellowish hue, and exhibits the following composition—

Carbon	28·07
Hydrogen	3·32
Nitrogen	10·92
Oxygen	57·69
	100·00

This compound, to which M. Bechamp has given the name of *tetranitric cellulose*, is not soluble either in alcohol or in ether, but if a little ether be added to the alcohol, or a little alcohol to the ether, it dissolves rapidly. Water precipitates it in bulky flakes, which do not unite together in drying.

This variety of gun-cotton is, in a photographic point of view, very important.

A collodion has been recently introduced in which alcohol is in much greater proportion than the ether. Our experiments do not confirm the claims set up for this article by the promoters, but that says nothing. However, if our suggestion is worth any thing, we recommend those who are engaged in its manufacture to make use of a pyroxyline which has remained for an hour in ordinary strong ammonia. The alkali must not be employed in excess, it is only necessary to impregnate the cotton with it.

At the expiration of the time previously indicated, the gun-cotton must be washed in abundance of water and dried. It is then soluble in a mixture of one part ether and nine parts alcohol.

Trinitric cellulose is obtained, according to M. Bechamp, by the action of caustic potassa upon the ethero-alcoholic solution of pyroxyline. Like the other, it is insoluble in ether, but the addition of a little alcohol determines the solution. Concentrated alcohol dissolves it at ordinary temperatures. Water precipitates this solution with difficulty, and the precipitate, which is very tenacious, unites together in drying.

The solubility of gun-cotton increases with the elevation of the temperature of the acids, but it must not exceed 212°. To obtain a good pyroxyline, it is indispensably necessary to immerse the cotton in the liquid immediately the saltpetre has acquired a clear syrupy consistence with the sulphuric acid; the disengagement of heat being much more rapid in proportion to the intensity of the reaction, it is necessary to reduce the saltpetre to a very fine powder.

New Methods for the Preparation of Photographic Pyroxyline.

Theory and experiment both show, that to obtain good gun-cotton, not only soluble in alcoholised ether, but which will also give a good adherent coating on glass, there must be no excess of sulphuric acid, nor must the temperature be either too high or too low. Upon these principles the following method is based, in which we employ a mixture of nitric and sulphuric acids, but modified as shown:—

Nitric Acid—The nitric acid of commerce is a colourless liquid, of a peculiar odour, and which stains the skin yellow. Commercial nitric acid is generally pure; the impurities it may happen to contain do not usually influence the successful result of our process, which is important. It generally, however, contains foreign substances which may be seen floating in it. When left to repose, these floating matters subside, and the clear portion is decanted into a retort, and boiled until the temperature reaches 253° Fahr., using the necessary precautions familiar to chemists.

A thermometer, graduated in the tube, must be immersed in it from time to time, and when it shows that the temperature of 253° is attained, the action of the heat must be stopped, the retort removed, and allowed to cool gradually.

When at the commencement of this operation, the retort has been completely filled, more than half the liquid must be evaporated before it will attain the temperature of 253°. By adapting a receiver to the retort, the acid passing over in the state of vapour is condensed.

The object of this operation is to concentrate the nitric acid. The usual density of nitric acid is seldom more than 1·42; it then contains four equivalents of water.

Sulphuric Acid—The ordinary sulphuric acid of commerce is usually strong and pure enough for our present purpose.

Cotton—Carded cotton is the best. It is only necessary to pick out any mechanical impurities it may contain.

Gun-cotton is prepared with the above-named acids in the following manner:—Measure twelve drachms of nitric acid, specific gravity 1·45, and pour it into a suitable glass vessel: then measure twenty-four drachms of sulphuric acid, and add it to the nitric acid. As the temperature of the mixture rises suddenly, it is advisable to place the glass vessel in a porcelain dish, so that in the event of the glass breaking the acids may not be spilled.

A thermometer plunged into the acids at the time they are mixed, will show a temperature of 160° to 175°. Stir the mixture with a stout glass rod, and allow it to cool until it reaches 140°. Then put into it, five or six grains at a time, about fifty grains of cotton. Every time a portion of cotton is put into the acids it must be pressed against the sides of the vessel, in order to expel the air, and that the cotton may be thoroughly acted upon. When all the cotton is immersed, withdraw the rod and the thermometer, cover the vessel with a plate of glass, and allow it to stand ten minutes.

At the expiration of this time, transfer the acid into another vessel, squeezing out the excess of acid from the cotton with the glass rod. The acids will serve again for thirty grains of cotton if three drachms of sulphuric acid are added. The cotton is then washed in water containing one per cent. of aqua ammonia, then in pure water, and afterwards dried.

The operation must be performed quickly without interruption; the liquid should not become colder than 120°. The gun-cotton thus obtained is completely soluble in alcoholised ether, and flows freely on the glass. Its colour is yellowish white, particularly if it has been washed in ammoniacal water.—*Bulletin of the Paris Photographic Society.*

CARBON PRINTING.

By M. Alphonse de Brebisson.

Dissolve six or seven parts of fine gelatine in one hundred parts of a saturated solution of bichromate of potash, in a porcelain dish, heated by a spirit lamp. Float upon this a sheet of strong glazed paper, and suspend it by a corner to drain and dry.

When dry, place it in a printing frame under a negative. An exposure four times less than that required for chloride of silver will suffice, and diffused light answers very well. If the lights are solarised, the carbon will not adhere to these points.

When sufficiently exposed, I take the proof into a dark room, and place it, picture uppermost, upon a glass plate, and fasten it at the corners with gum. Then with a tuft of cotton dipped into carbon I cover the proof with a uniform layer of the pigment: either dry lamp-black, or black-lead, red-lead, or other pigment.

The proof is then removed from the glass-plate, and placed in a dish, and a quantity of boiling water poured into it; and by means of a tuft of cotton or soft brush passed over the whole surface, we remove the excess of carbon, and clear the lights, which is very quickly accomplished. Washing in abundance of water completes the operation.

Some operators apply the black to the paper before exposure to light, but comparative experiments have proved that this practice injures the influence of the light. These proofs are far from possessing the delicacy of those on chloride of silver. The effect of the friction of the cotton imparts a leaden aspect, very cold and disagreeable. A fine intense black carbon is necessary, the particles of which do not blend with each other like those of plumbago, which gives an unevenness and uncertainty to the outline, and deprives the pictures of sharpness. This art is as yet in its infancy, and we have everything to hope from the future.

It is a great thing to be able to obtain permanent proofs rapidly and at little expense.—*La Lumière.*

REMARKS ON THE NITRATES OF IRON.

By A. Scheurer-Kestner.

When the solution of a nitrate of iron is left to itself for a while, it sometimes becomes gelatinised and appears opaque. In diluting the solution thus modified with water, the jelly disappears, and the liquid becomes limpid by transparence and thick by reflexion, having much analogy with ferric acetate modified by heat. We know that the allotropic modification of oxide of iron has been obtained from ferric acetate, by submitting this salt to the prolonged action of heat at 212° (?). With the same object in view, I have submitted to the action of boiling water neutral nitrate of iron and the two soluble basic nitrates. These salts were enclosed in sealed tubes, and plunged into boiling water. At the expiration of some hours the colour of the two basic salts was considerably modified: it had passed from brown red to brick red—the solution, limpid by transparence, appeared thick by reflexion. Upon opening the tubes no odour of nitric acid was perceptible but the basic salts had acquired new properties. A drop of sulphuric or of hydrochloric acid, or of a solution of sulphate of soda or of potash, gave rise to a precipitate; while, before being submitted to the action of heat, these salts were precipitated only by concentrated nitric or hydrochloric acids, and not by sulphate of soda. After ten hours ebullition, a portion of the tribasic nitrate, $Fe^2\,O^3\,NO^5$ separated from the precipitate by means of sulphate of soda, yielding upon analysis the following numbers:—

12.525 grs. of the liquid produced 1.186 grs. ferric oxide, and 2.022 carbonate of lime = 2.2039 grs. NO^5, or in hundredths—

NO^5	17.60
$Fe^2\,O^3$	9.88
Water	72.52

The oxide of iron and the nitric acid are found in the relation of 1 : 1.781, while previously the relation was : : 1 : 0.68. At the end of seventy-two hours' exposure to heat, the liquid separated as before, presented the composition of nitrate of iron and three equivalents of acid. At this point the action of the heat stops: the neutral nitrate is not modified even by exposure to boiling point of water for 144 hours. Therefore, the two basic salts only are susceptible of modification.

The precipitate obtained by sulphate of soda, dried upon glazed porcelain, by means of a current of dry air, formed little black scales, insoluble in concentrated acids, but very soluble in pure water, yielding a solution thick by reflexion and limpid by transparence. This remarkable solution no longer gives, with the ferro-cyanides and the sulpho-cyanides, the characteristic reaction

of the salts of iron, and may be reprecipitated by the acids and by sulphate of soda, in reproducing anew soluble oxide of iron. By calcination this oxide has yielded the following numbers:—

0.583 of the substance produced 0.524 of oxide; or

$Fe^2 O^3$	89.88
HO	10.12

The formula $Fe^2 O^3$ HO requires

$Fe^2 O^3$	89.89
HO	10.11

Oxide precipitated after 144 *hours ebullition.*

0.682 of the substance produced 0.626 of oxide; or

$Fe^2 O^3$	91.70
HO	8.30

Thus heat exercises upon the two basic nitrates an action analogous to that it produces upon ferric acetate, but with this difference, that while the ferric acetate is completely decomposed into ferric oxide and acetic acid, the basic nitrates are decomposed into oxide and neutral nitrate, the latter salt resisting decomposition.

Light exercises the same action as heat upon these bodies, and it is to that agent we must attribute the decompositions sometimes produced in solutions exposed some time to the air. Three bottles, properly corked, and containing the three soluble nitrates, were submitted to the sun's rays for five months (from 21st December, 1858, to 21st May, 1859). The neutral nitrate of iron had preserved its limpidity and its original composition, while the two basic salts were in great part modified. Even after three months exposure the liquids had become precipitable by sulphuric acid and sulphate of soda. The same salts purposely placed in obscurity during the same period of time were perfectly preserved, without undergoing any change in their composition.

It will therefore be seen, that there exists a notable difference between the decomposition these salts undergo from the heat of boiling water, and that excited by their own ebullition: since on the one hand they are decomposed without loss of the elements, while on the other they separate into a salt more basic and free acid which is disengaged.

THE HAZE AND CHARACTER OF THE ATMOSPHERE, IN THEIR PICTORIAL, DIURNAL, AND CLIMATERIC RELATIONS, IN REFERENCE TO HELIOGRAPHY.

By Dr. Lotsky.

It is photography *itself* which may prove that apparent paradox—that scientific, industrial, and art inventions and contrivances have *reached*, or almost have reached, their culminating point, and that their universal spreading (popularisation) is *the* performance next following of that drama we call human history. However this may hold good in a general point of view, the haze and character of the atmosphere at different hours of days and seasons, and in different climates, are subjects lying, methinks, at the confines of man's indomitable and practical power.

It is not the *sky* part of Great Britain which makes her what she is in other respects; at least there is not much very artistically characteristic in the haze and glare of the hours and seasons, as they wheel round about us. As we have to discuss, in the present paper, this subject as far as it relates to three, or even four parts of the globe, we may as well leave the English part of it to those who have had an opportunity of dwelling amongst the knolls and rocks, the heather, the bays, and the mountains of old Albion. Besides, these mysteries and secrets of nature are not to be arrived at but by a close intercourse with her, by those whom some intention or other may keep enthralled, as it were, for years and years amongst what Humboldt repeatedly called "God's *free* nature."

Beginning, therefore, with the sub-alpines and meadows of Germany, extending over so vast an area, there are scenes and moments of great ideality to be met with there. I well recollect one summer sun-rise, amongst the wooded hills and rocky dales of Bohemia, where the thinnest ethereal mist extended over and burst forth, sun-gilt, from the lateral valleys of the tract over which I was travelling on foot; while the sun-throned light lies veiled somewhat above the horizon, and, in fine, burst forth in all his glory, still more superinfusing with his gold the rolling and heaving waves of the mist-like haze. Göethe, who had witnessed similar scenes, says:—

"Aus *Morgenduft* gewebet und Sonnenk larkeit."*

Such a scene given on a large plate by the collodion process would be surprising; but we have to leave it with the practical *heliographer* whether it *can* be done at all. Laying before the artist new scopes and new stand-points for exertion and performance, it is this theoretical part of the vast art-science of heliography which may incite invention, and indite new paths for improvement. The grand atmospheric phenomena of the Alps offer still grander gradations of the kind; but the difficulties for photographic seizing are also greater, and must be left to the future.

I shall not dilate here on the famous and gorgeous sunsets of Paris, as seen from the Tuilleries Gardens, &c., being familiar to most of my readers. Proceeding thence to the South of France, it is at Lyons where a notable change of light and atmosphere is observed. If one leaves Paris at the beginning of April, when everything is yet nearly hibernal, and runs down to Lyons and meets with fine weather and a complete spring, the observation of atmospheric diversity will be stricking. Looking from the windows of one of the hôtels on the Rhone on the splendid gothic edifice of the Cathedral, we perceive that we have reached another feature of European nature—the south transalpine. There is in the morning hours a certain most tender sunny haze and glare surrounding every object in view; and the shades of these many cornices, finials, &c., are projected in quite a peculiar way, very different from that in our northern climes. Göethe, who possessed the gift of the most delicate observation, alludes to this peculiar condition of Italian (southern) atmosphere in the most pointed manner, during his Italian journey, and on several occasions. He writes from Palermo:—"The vegetation presents altogether a peculiar green colour which we are not accustomed to, either more yellow or more blue than with us. But what imparted to the whole sight a most wonderful charm, was a sort of strong breath (starker Duft) or haze which was uniformly diffused over the whole, so much so, that objects even only distant a few paces from each other were separated by a light blue glare or haze, and thus their natural colours almost vanished away, or reached the eye with a peculiar blue admixture. What wonderful effect such a haze imparts to distant objects, ships, and promontories, is very remarkable to an eye experienced in the picturesque, as the distances of objects are to be calculated, nay ascertained; wherefore a walk on these heights was exceedingly charming. One does not see any more nature, but rather pictures, that the most skilful painters could not have perspectively separated by any ingenious process. [*Lasiren.*]"

It is true that Claude Lorraine, Poussin, and Turner have, in several of their pictures, endeavoured to render this peculiar, dreamy, phantastic appearance of the southern atmosphere; but I venture to express the opinion that they have never reached it. It is an object worthy of the experimentalising and thinking photographer to see, whether by any of the extant processes or any one yet feasible this peculiar climateric nature-illumination could be fully rendered or approached, always understood to be assisted and completed by some subsequent colouring and tinting process, yet *hidden* in the womb of time.

Whenever the time shall have come that *Itineraria Photographica* and similar *Pracht-Worke* (splendour-works), as the Germans call them, shall be contemplated, works illustrative of the traces of *great men* will occupy a conspicuous part of photographic literature. But nothing can ever, in sublime inland scenery, be compared with *Vaucluse*, where amongst mountain solitude Petrarch passed many years of his life. It is a valley picturesquely winding, surrounded by hills covered with all the fairness of southern vegetation; and in the back ground rises the giant rock pyramid, nearly 800 feet high, out of the spacious cavern of which issues the fountain of the *Sorgue*, then meandering through the valley. Some remains of Petrarch's dwelling-place enhance the fairness of this sight, almost constantly superfused by the sun-glare of a Provence sky. Whenever the art of tinting (and colouring!) shall have been brought to perfection, such heliographic plates will range amongst the fairest ornaments of our dwellings.—Proceeding south, in *la belle France*, the *Vista*, near Marseilles, called by some *Marseilles en Afrique*, claims our attention. It is the elevation where the sea and town are perceived first by the inland traveller—a sight so grand, that it forcibly struck the great landscape painter *Vernet*, who afterwards painted *Antibes*, with its orange-groves. There is a grand perspicuousness and pellucidity and vibration of the air, if we may say so, observable in many of those Mediterranean seasides and sea-views—an expansiveness of the sun's glare, which made them the favourite haunts of Byron, Shelley, and Keats. The view also from *Notre Dame de la Garde*, ranging over a wide expanse of the Mediterranean, which, when quiescent, is rippled and furrowed by some hitherto unexplained streaks and lines, will yield plates worthy of that approaching national and people's *art-life* and art-enjoyment we all have so much at heart. The towering rocks

* Woven out of morning perfume (?) and sun clearness.

bounding the seashore of Marseilles will be the more interesting subjects, as it were those which the Carthagenians, in times of old, skirted in their then rude yet daring crafts. In genial seasons and weather these places swim in a glare and haze of the fairest light and balm.

CELESTIAL PHOTOGRAPHY.

We have received the following note from our friend Mr. De la Rue; and though the corrections given below are rather amendments of awkward phraseology employed, consequent upon the hasty manner in which reporter's notes are of necessity taken, than upon matters of fact, we the more readily insert them because of the very interesting nature of the paper itself, which we are anxious to make as complete as possible :—

110, *Bunhill Row, London, E.C., October 3rd*, 1859.

My Dear Sir,—I have sent you by this post a copy of your Journal with corrections of your reporter's account of my communication. It is wonderfully faithful, and gives a good summary of my paper, which I curtailed considerably in reading, in order to allow of other communications being read in section A, before which there were a great many papers on the day I gave an account of my doings. Yours very sincerely,

George Shadbolt, Esq. WARREN DE LA RUE.

Meetings of Societies.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

The Ordinary Monthly Meeting of this Association was held at Myddelton Hall, Islington, on Wednesday the 28th ultimo.

George Shadbolt, Esq., Vice-President, in the Chair.

The minutes of the previous meeting having been read and confirmed, the Chairman stated he had received a very interesting paper from one of the members, Dr. R. L. Maddox, *On the Paraffine Paper Process*, which he then read to the meeting [see page 235], and also the following note relative to the same subject, which he also read, and exhibited many of the negatives on paper produced by the author : —

"*Woolston, September* 27, 1859.

"Dear Sir,—If on perusal you do not condemn me as trying to encumber your *embarras des richesses* for to-morrow evening, perhaps you may have an opportunity just to allude to a fact, which hitherto I am not aware of having been before noticed (on this I may be wrong), and possibly eventually assist us in perfecting some "Modified Waxed-Paper Process." Iodide of zinc I find to be soluble in belmontine : this did not surprise me, knowing that the metal combines with the alcohol-radicle, as we have zinc-methyl, ethyl, and amyl, yet I anxously waited the opportunity to test its photographic powers on paper prepared with it and *Japan vegetable wax*, on which you certainly must deem me rather favourably impressed, *n'importe*. As a comparison I tried also the Japan vegetable wax with belmontine, combined with iodide and bromide of ammonium, on papers prepared with albumen according to the plan suggested by you in the Journal for August 1st. Belmontine, six oz.; Japan vegetable wax in shreds, two drachms; iodide of ammonium, thirty grains; bromide, six grains, each crushed. Bottle set in hot water and shaken repeatedly; filtered after eight hours. Turner's albumenised paper soaked in same for twenty minutes, dried suspended, sensitised after formula in my former contributions to your Journal, floated on water, dried, exposed one and two minutes dull light, Voigtlander ⅝ central stop, and 23-36 seconds, &c. Again — belmontine, six oz.; Japan vegetable wax, 1½ drachms; iodide of zinc, twenty-seven grains; iodide cadmium, six grains. The iodide zinc dissolved readily; the cadmium appears to be much less soluble—no free iodine used to either solution. Turner's albumenised paper soaked in this twenty minutes, exposure as marked on back, *i.e.*, one minute and a-half, moderate sunlight, developed with pyrogallic acid, six grains; glacial acetic acid, one and a-half drachms; rain water, six oz.; two drachms of this—one drachm of saturated solution galic acid, with Beaufoy's acetic acid, and a few drops of twenty grains solution nitrate of silver. I am sorry that they are not better focussed, but one of my slides is not quite correct, and I have a difficulty without trial to make the proper correction if the thickness of glass used in the slide at all differs. However these are the negatives, *un fait accompli!* and as they are the first, why please look on them with indulgence. The iodide of ammonium one developed very slowly, half-an-hour, at which time the developer was not discoloured; the iodide zinc one quickly, twelve minutes, the solution slightly discoloured. It really seems worth while to run over some of the other metalic iodides, and also to try other developers, which if all be well I may ere long attempt, and trust to the pleasure of communicating the same to you. Thanking you for all past favours, and wishing hearty success to the Society and Journal under your auspices, I remain with compliments, dear sir, yours faithfully,

"R. MADDOX."

A vote of thanks was accorded to Dr. Maddox for his paper, &c., and an animated discussion eusued.

Some *very* beautiful photographic copies of prints were laid on the table by the Secretary for the inspection of the members.

Mr. Shave exhibited some superior stereoscopic pictures—scenes in North Devon, &c., taken by the Fothergill process: there was an entire absence of stains and markings, which caused much inquiry. Mr. Shave was of opinion that the cause of success was to be attributed to using a collodion specially prepared for the purpose, as he had not taken more than ordinary care in the preparation of the plate.

Mr. Hislop exhibited pictures 9 × 7, wet collodion (orthoscopic lens), taken in the neighbourhood of Edenbridge and Tonbridge. They were much admired for their beauty of detail and general artistic effect.

A large photograph was presented by Mr. Moens for the portfolio of the Association. Thanks were voted to him for his present, to the gentlemen who had exhibited pictures, and to the Chairman. The Meeting then adjourned till October 26th, when Dr. Ryley *has promised* to communicate the result of further experiments on his *Modification of the Collodio-Albumen Process.*

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

Members are reminded that the first meeting of the above Society for the ensuing session will be held in the large room adjoining the Lecture Hall, Carter Street, Walworth, on Thursday the 20th inst., when gentlemen desirous of joining are requested to attend.

Letters for information respecting the exhibition of apparatus, reading of papers, or terms of admission, to be addressed to the Hon. Secretary, Mr. A. H. Wall, 11, The Terrace, Walworth. S.

Photographic Society of Scotland.—In our advertising columns will be found an advertisement announcing the fourth Annual Exhibition of this Society, which is intended to be opened at Edinburgh on the 16th December next.

NOTES OF A PHOTOGRAPHIC TOUR IN THE HOLY LAND.

No. VII.

We remained four days in the Jordan Valley. On the morning of the fifth a pleasing incident occurred which is worth relating. We rode down to the Jordan at the pilgrim's bathing place—the spot where it is said Christ was baptised—and we stood on the bank, watching the flow of the river, while I described to John the amusing scene I had witnessed on my previous visit, when the pilgrims were rushing in, and bathing and dipping their shrouds in the sacred stream. The appearance of the river was different now. Its calm flow, the still and lonely banks, the soft gush of the holy water, were unlike that scene when pilgrims of all nations thronged it and sought purity in its stream.

As we stood there, lost in contemplation, a shout from across the river, in pure English, startled us.

—"Who goes there?"

Think of an Anglo Saxon salutation in the land of the Moabites! Who think you it proceeded from? From John's next door neighbour and most intimate friend. He was with a party who had come down from Jerusalem the day previous, camped at the head of the Dead Sea, and were now riding up the Valley, having forded the Jordan to say that they had been on the other side. Catching sight of us, they had hailed us in their own tongue. The

meeting was joyful, and we passed the morning together. They went back to the Holy City in the afternoon, while we struck our tents and rode over to Saint Saba's in the wilderness, where we passed the night in the ravine outside the convent walls. I had tried the inside once and that was enough for me.

The next day we rode to Bethlehem, aud slept in the convent that night, and thence came by the pools of Solomon down to Hebron.

The road from Jerusalem to Hebron lies by Bethlehem. As John desired to see the mosque of Machpelah, I of course accompanied him, and secured a good picture. Therefore I date this letter from the city of Abraham. Possibly my tent is pitched on the identical ground that was occupied by his tent, when the promises were made to him which had their fulfilment in the glorious history of his children — which are yet to have their further fulfilment in the future history of that despised but powerful race, whose children are more numerous to-day than in any former generation, and who are steadily and constantly surpassing the host of heaven in number.

Here, where my tent is pitched, the angels came. Here the patriarch began his weary travel to the hill Moriah, where Isaac was to be sacrificed. Here the story of Hagar had its origin. Here Ishmael and Isaac buried the Father of the Faithful.

The mosque of Machpelah, a Mohammedan building, is jealously closed against Christians and Jews. Rumour has it that last year three American gentlemen and a lady succeeded in effecting a partial entrance, but before they had accomplished their object the citizens, having got wind of it, assembled and surrounded the mosque with hideous shouts, bringing out the travellers, the gentlemen with revolvers in their hands, and that they escaped with their lives only by exhibiting their weapons and evincing a willingness to use them.

The cave of Machpelah is one of those places around which the most interesting of all associations linger. No race of civilised men exists to whom the burial-place of the patriarchs has not more or less interest.

That there is a cave under this great mosque on the hill side in Hebron cannot be doubted. It is a large dark cavern, described more or less minutely by two or three travellers who profess to have seen it. My own Arabs, who go in and out of the mosque freely, speak of it as a vast cavern, into which no one is allowed to enter, and they know nothing of its contents. As usual in Moslem countries there are a dozen small tumuli, like rude graves, or something of that sort, in the open court of the mosque, and nothing more. These are named after the various patriarchs and their wives, who "rest in peace."

Hebron is a scattered city, in a long and somewhat winding but very fertile valley. In the lower part of the town are two ancient pools, doubtless the same spoken of in the Bible, over one of which David hung the murderers of Saul's son.

In the city are some three or four glass-making establishments, but on a small scale, affording employment to not more than twenty hands each. Most of the labourers are employed in the fertile fields of the Valley of Eschol, whose vineyards are as rich and grand as of old. The streets are narrow, dark, and very filthy. The great mosque stands on the edge of the lower part of the city, nearly surrounded by houses.

The locality of Hebron has never been lost, and the Cave of Machpelah cannot be mistaken.

I am always falling into scrapes, and my usual luck attended me here.

Accompanied by Hassan I strolled through the town in search of eligible photographic sites. There are some parts of every city on earth into which if a stranger goes he will be likely to fall into trouble. But Hebron is all alike in this respect. My ignorance of Arabic was my protection in this as in former instances. I found myself penned literally in a corner. About thirty of the rascally Hebronites had surrounded me, and I took refuge in the sharp angle of two houses and stood at bay, with a revolver in each hand, ready to fight it out. Hassan had run out of the city gate as fast as his legs could carry him, to look for John, shouting "Howajji Yehyeh!" and soon returned with my formidable friend, running in double quick time.

One of the rascals had taken up a stone, as big as his fist, to throw at me. I immediately covered him with my revolver, when my eye caught sight of John's felt wide-awake.

"I say John, just tell that yellow-skinned rascal that if he don't drop that stone in three seconds, I'll drop him!"

The successor of Ishmael had not appreciated the danger of his position until John explained it, and then he and the stone fell together. He was utterly astounded at the danger he had escaped, and the more so when I gave them a little specimen of the man they had to deal with. John assured them that I carried in my hands and pockets the lives of half Hebron, and that he had the other half in his.

"Show them a little sharp-shooting, parson," said he, taking off a dirty tarbouche from the head of a boy, and tossing it into the air. Crack went my revolver, and down came the cap with two holes in it. "*Mashallah!*" shouted a dozen voices. John gave it back to the boy with some coppers to pay for mending the holes in it. The crowd respectfully withdrew and allowed John and myself to walk off unmolested.

"How did it happen, parson?"

"I really dont know! These dogs don't understand my tongue and I dont understand their's, and mistakes are natural. I was rambling down a street, and lost my way: hailed an old fellow with beard and turban, and when he went by me without replying I overhauled; he yelled; thought perhaps I was Satan: his townsmen came to his rescue, cornered me, and the temptation to fight it out was irresistible when you came up."

If ever you expect to visit Moslem lands, let me beg, if you value your peace of mind and sanity of body, not to go without some such stalwart champion as my friend John Weston. It is impossible to avoid getting into difficulties; and a Moslem mob is very daring in the presence of a solitary infidel, whereas two are almost as good as twenty. We never go out without two six-shot revolvers a-piece, and as we never miss aim or fire, there's a couple of dozen foes *hors de combat;* and sometimes John carries three with him, making thirty-six shots in all. Verily, eastern travellers are very much indebted to Mr. Colt for his invention.

A mile or so up the valley from Hebron is a vast tree, said to be the Oak of Abraham, whereof there are various traditions. It is a fine large terebinth tree, venerable enough looking to pass for a contemporary of the Father of the Patriarchs; but, if the truth were known, I suppose it would prove not more than four or five hundred years old. A little way from this, on the road to Jerusalem, are ruins called the house of Abraham, where the Moslems say his dwelling stood. They are probably the remains of a mediæval church or convent.

I have spoken of the glass factories of Hebron. These manufacture scarcely anything but small bottles and rude glass beads and bracelets — the latter being mere bands of coarse coloured glass, but they form a great item in the trade of Holy Land, and passing caravans distribute them from Cairo to Damascus.

As evening fell on this old valley, so soon as I had been rescued by friend John, we took our seat in our tent door, imitating the father of Isaac, and waited for angels. With the starlight they came, the angels of peace and joy — delicious memories of home!

One by one the grand events in the history of that valley of Mamre passed before us. The scenery of Abraham's life, his purchase of a grave, his death and kingly burial, the life of Isaac, the strife of Jacob and Esau, the burial of their father, the royal pageant that came up from Egypt to bury Jacob — then scenes in the life of David when he held court in Hebron, and then — even as we sat together and talked, while the stars shone on us, and a moonlight that Leah might have loved, silvered the minaret above her tomb, we grew silent and heard — I heard — the lapse along its banks of the sedgy Ouse, far away, and the voice of one beloved; and wrapping my cloak about me, and falling back on my camp bed, I slept calm, deep, and blessed sleep.

Once in the night I awoke. A low murmur of voices outside the tent had disturbed my visions of far lands. The door curtain was raised as I had left it, and I could see Hassan and his followers sitting around the camp fire, their eyes flashing in the changeful light as they watched the dark hours through. I knew that he would not sleep till I arose in the morning, so I lay back, and with my eyes fixed on the strange group, lost consciousness, and slept again. Now my dreams were troubled and I awoke at dawn.

As the sun rose I walked out on the hill back of the Quarantine Station, and breathed the fresh south air that came up from the desert. Hassan followed me, and begged me to go down to Wady Mousa and the Rock City. It is but four or five days gallop from Hebron, and we could do it easily, he said, and his people would rejoice to welcome us among the Alaween. The temptation was great, but I decided for the present to postpone a visit to the valley of Moses.

So here in the morning, on the plains of Mamre, I have added this letter to the pile in my folio, waiting an opportunity of forwarding them to you. When will the East have its Rowland Hill?

D.T.

Practical Instructions on Coloring Photographs.

By Alfred H. Wall.

CHAPTER V. *(continued).*

The Use of Water Colours.

Upon glass positives water colours should be seldom used, as their effect upon such surfaces will always be strikingly inharmonious and offensive to good taste, although a touch or two may sometimes be carefully applied to produce the sparkling high lights of jewellery, lace, &c., as I have already stated, and are also, as I shall explain, necessary in the treatment of certain defects.

TO COLOUR AND IMPROVE AN INFERIOR POSITIVE.

To do this may very frequently (as in the case of a bad picture being the sole relic of a deceased relative or friend) be most desirable. Suppose, then, we have before us one of those leaden-hued ghostly positives, which somebody has bought very dearly at an exceedingly low price. Here it is in all its ugliness, either pallid and indefinite in a thick white fog, or sooty and begrimed in a black one. Suppose it to be the former. In the first place, if necessary, we "put in the eyes" with a fine sable pencil and a little Indian ink, carefully strengthening the line round the iris, and touching in the pupil with a neat clean touch; the eyelids and lashes may be marked with the same, and, if required, the nostrils and line dividing the lips also. This done, take a little of the powder grey, and with it strengthen the barely visible half-tints, doing the same for the lights with the powder white, being careful *not to touch the wet with the dry colours*, as the latter would adhere to the former far more strongly than to the collodion surface, and would not admit of softening. The hair may be strengthened with the Indian ink, and then the varnish can be applied; after which, proceed to colour as usual.

And now suppose we have the "under-developed" and "under-exposed" positive (the black one) to operate upon.

The sockets of the eyes are a dense black mass, in which the optics are nearly or entirely lost. To bring them out, use Indian ink and Chinese white (water colours)—the former for the markings or drawing of the eye; the latter, with very light careful touches, for the lights and the white portion of the eye. Next take your dry white and work it into the high lights, and mixed with a little grey into the half-tints, until the image begins to show some little signs of roundness, although it now appears a very coarse chalky smudge. After this, varnish and colour as usual.

But although thus much may be done to remedy these defects, *such* productions cannot be *much* improved by any process.

COLOURING GLASS POSITIVES IN OIL.

Oil colours are used with most effect and greatest ease on paper, but as they are also frequently used upon collodion, I may as well inform you that it is advisable to coat the picture with pale drying oil, and allow it to dry before commencing the colouring. Practical details may be looked for in my future chapters upon colouring in oil.

COLOURING ALABASTRINE POSITIVES.

Although these positives have a delicacy and beauty peculiarly their own, they have also a cold chalky appearance, both before and after colouring, which render them no especial favourites of mine. I doubt also if they are permanent. Although we decline taking them, myself and partner purchased the secret of producing these pictures, but we might have obtained the same for a very trifling expenditure had we known that in Archer's pamphlet on the Collodion Process, published in 1854, the method had been fully described. Positives whitened by the usual saturated solution of bichloride of mercury have a cold bluish tint and will not receive the ordinary varnish without turning deeply (but not beautifully) blue. Although it is somewhat out of my province, the reader will perhaps thank me for quoting the passage above referred to from Archer's little book:—

"Before commencing the process of whitening a picture, it should be considered whether the collodion with which it is made is strong enough to bear without injury the application of the very corrosive compound employed.

"The acid solution of corrosive sublimate would very soon destroy the little remaining tenacity of a weak collodion, and the operator would have the mortification of finding that his picture, although able to bear the application of the whitening solution, would fail altogether to resist the action of water in the after washing.

"To resist, therefore, the rough usage the picture will have to undergo, it should be made with tolerably strong collodion.

"Prepare, first, a saturated acid solution of corrosive sublimate (bichloride of mercury):—

Bichloride of mercury	2 drachms.
Muriatic acid	2 "
Water	6 "

"This will form the normal solution, to be diluted when occasion may require.

"After thoroughly washing the picture to free it from fixing solution, and while still moist, cover it rapidly at one motion with a weak solution of bichloride of mercury, made with—

Saturated solution (bichloride of mercury)	1 part.
Water	10 parts.

"After the plate is fairly and evenly covered, the greater portion of this liquid is drained back into the cup, and a drachm of the saturated solution is added to it and applied, after which the picture will rapidly whiten.

"This operation may occupy from one to three minutes and sometimes longer.*

"When the whitest effect is produced the picture is carefully washed with a stream of water; afterwards put by to drain, protected from dust, to be varnished with white lac varnish."

Such is Archer's process of producing what *he* calls simply enough "whitened" pictures, and *we* term "alabastrine."

In adition to the above I will add, that the time occupied in whitening may be shortened by putting the plate upon a gilding stand, and *gently* warming it by the application beneath of the spirit lamp — that the positive *must* be a good one — that it should not whiten too quickly — and that hot water is best to free it from the solutions, after which it may be rinsed in cold.

The lac varnish recommended should not be used for colouring upon, but in its place one compounded of benzole, gutta-percha, crystal varnish, &c., but which however can be more easily purchased than prepared;† the colouring is not commenced upon the collodion, in consequence of the metallic deposit upon the surface, but after varnishing.

The method already given is that to be adopted in the colouring, except that a general increase of warmth in the tints is desirable; the new absorbent colours answer excellently for these pictures, and, in fact, are as effective upon any of the varnishes used for colouring as upon a surface prepared with the solution more particularly intended for them. Black varnish quite destroys the beauty of alabastrine pictures, they should therefore be backed up with a rich maroon velvet. In fitting them into cases, SECURE them from the air with gummed paper.

NON-INVERTED CHROMO-PHOTOGRAPHS.

Alabastrine pictures after being coloured may be treated with a preparation, sold by Mr. Newman, of Soho-square, under the name of "penetrating varnish," which has the effect of rendering the colours visible upon the side contrary to that upon which colour has been applied. These pictures, apart from the advantage of being non-inverted, retain the minutest details of the photograph, which is in this case *on* instead of *under* the colour. It is evidently important that the whitest glass should be used, and that the tints selected should be from the more powerful, as also from those which receive the most permeating power from the "penetrating varnish." Some few experiments will best decide the latter point, as the results are variable.

The author of the preceding paper has, in order to render his communications of greater practical value, kindly undertaken to criticise the work of, and give advice to, students in colouring through the medium of these pages, for which purpose specimens may be sent, with a stamped and directed envelope *for their return, to* A. H. Wall, Esq., 11, The Terrace, Walworth.

G. R.—The new absorbent colours may be varnished in the same way as others. As you say, it is no small advantage to finish the colouring entirely before varnishing, for not only are the colours more permanent, but when viewed obliquely they have not the chalky smudgy effect which such colours necessarily have when unvarnished. This is one of the greatest advantages offered by Messrs. Reeves's new colours.

Miss D. (Kingsland).—Use your medium thinner or more freely, as your colour is laid on too thickly. A proper body of colour on the lights does not necessarily imply coarseness; and although mere smoothness is a quality scornfully and suspiciously regarded by critics, it pleases the general public, and is no real disadvantage. With regard to your other questions, pardon me if I refer you to the forthcoming chapters upon colouring in oil. Read the Maxims *again.*

M. (Guernsey).—For practice colour upon large heads, use less colour in your brush, and work in smaller circles. I am most happy to have been of such good service to you. A. H. Wall.

* Generally longer; much longer is I think best for the result.

Letters to a Young Photographer.

No. XXI.

MY DEAR EUSEBIUS,

The third element in the imitation or representation of an object is *colour*. Colour is to Form what Music is to Poetry. In the poem or the statue we have the thought, and the form embodying the thought, the representation of the idea: music and colour clothe the thought in melody and harmony, and the utterance is then for the artist, now completed in the song, the symphony, and the picture.

Colour is a word that has a much wider signification than the common acceptation of the term. It is composed of three elements: of *light*, which is a condition of colour; of *tint*, which indicates its hue or quality; and of *tone*, which indicates its intensity, and is distinct from light, and independent of tint. The genius of a colourist is displayed in his knowledge of the due relation of tones.

Colour, as a means of imitation, is more complex than outline and relief. Most artists entertain the idea that colour is the principal merit in a painting. Where one aims at success and popularity by means of form, there are ten who seek it by means of colour; consequently there is at the present day a tendency and disposition to cultivate colour at the expense of the other two elements, outline and relief. The eye of the ignorant multitude is sooner attracted by the colour of a picture than by its other qualities; and imperfectly educated artists, knowing this fact, hasten to colouring long before they have learned to draw well, and even before they have scanned the rudiments of *chiaroscuro*. Our picture exhibitions are as gaudy as a tulip bed. The luminous colours so abound that the eye is dazzled and bewildered. We have a *brilliant* exhibition, it is true, where mechanical dexterity usurps the place of thought, and poverty of idea is sought to be concealed under the flimsy veil of cadmium yellow and artificial ultramarine. It is on this principle of construction that nine-tenths of our exhibition pictures are manufactured by painters who regard imitation as the end and not the means; but to whom we must, in justice to the thoughtful and conscientious, deny the title of artists.

Do not run away with the idea that I am decrying colour, my remarks apply only to the abuse of its powers and resources. Turner has no greater admirer or more devoted worshipper than myself. But I do not "cotton" to Etty. Turner was a grand experimentalist, whose every picture was a rush and a plunge into the unfathomable abyss of light, and had his rare natural instincts been governed and guided by science, he would doubtlessly have carried the art of colouring to its highest point of perfection. It is easy for any one acquainted with the laws of the harmony of colouring to see what Turner aimed at in his pictures, even in those considered the most extravagant by the uninitiated; it is also easy to see how the little knowledge he lacked would have carried him straight to a successful issue, and embodied on his canvas the aim he, in so many instances, vainly strived to attain. Like most great thinkers, Turner "swallowed all formulas," but he could not divert the laws of nature, nor apply them to his purpose without becoming acquainted with them.

Every object has its own peculiar colour, its *local* colour, as it is termed. This local colour is subject to numerous modifications, arising from the form of the object; from the nature of its surface, whether plain or polished, and from the reflexions thrown upon it from surrounding objects. If you take a cube of unpolished wood and place it in any open space upon a piece of black cloth, its local colour will be as little disturbed or modified as it is possible to be; but place it on a piece of white or coloured cloth, or carry it into a quadrangle constructed of white or coloured bricks or stone, and each side of the cube will undergo considerable modifications in its local colour, all of which would be appreciable in a photograph of the cube, much more so perhaps than to the eye. This is the simplest form of experiment. If we take a body of more complex form we shall have not only the influence of the surrounding objects in modifying the local colour, but we shall also have the reciprocal influence of these modifications upon each other; and a moment's reflection will convince you that these influences, which we call in their totality *chiaroscuro*, is a very difficult and complex affair.

Nothing is better calculated to educate the eye to a due appreciation of the resources of relief and *chiaroscuro* than photography. Its greatest achievements are attained without the adventitious aid of colour, and it has come most opportunely to rescue the public taste from its idolatry of that which only pleases but cannot inform or elevate its thought. I have before me some very fine engravings of architectural subjects, and good large photographs of the same, and I may say that it is through a long examination and careful comparison of the two modes of representation that I have arrived at a due appreciation of the complexities of *chiaroscuro*. And yet this is but half the subject: the complexities arising from colour are, in the present instance, wanting. You may appreciate the complexities arising from coloured reflexions mutually acting upon each other by the following experiment — Take a cubical box and colour the inside with differently-coloured pigments, let the bottom be blue, the two ends red and yellow respectively, one side green, and the other violet; place the violet side downwards on a table, and then cover it over with a piece of unglazed black paper, and look into the box, standing at some two or three yards distance. If the light be good you will see each side of the box modified in its local colour, not only in tone but in hue; and these modifications may be varied infinitely by substituting for the black unglazed paper, papers of other colours, and of white. It is not necessary to specify what these modifications are, but simply to observe them, so as to obtain a distinct conviction of their action and its importance.

Colour is a condition of light; without light there can be no colour. In painting we do not imitate first colour and then light, but confound them together, and produce both at the same time. We can produce the effects of light in a picture without the aid of colour, in the ordinary acceptation of that term, by means of perfect *chiaroscuro*, as may be seen in the works of Rembrandt, where the whole palette of the painter consists only of browns, and black, and white: a spot of white on the tip of the nose will bring more sunshine into one of his pictures than the richest palette Turner ever held. Therefore light can be imitated without colour, and the gaudiest colours may fail to produce the effect of light the artist aims at.

From colour as a condition of light we turn to colour as hue or tint. Our standard of colour is obtained from the decomposition of a ray of light by a prism, producing what is called the prismatic spectrum. This consists of six simple colours, three of which are termed primary, viz., blue, red, and yellow. Binary compounds of these with each other yield secondary colours, viz., green, orange, and violet. These prismatic colours are termed normal colours, that is to say, they are taken as the types or standard of colours; when we speak of blue, red, and yellow, we must understand these colours in their purity as they appear in the spectrum, and not as they are presented to us by our pigments, as Prussian blue, or gamboge, or carmine. None of our pigments, except ultramarine, are pure representatives of the colours of the spectrum. Most of our yellow pigments contain also blue or red, which gives them a green or orange hue. Most of our blue pigments contain also red or yellow, which gives them a violet or green tinge. While most of our red pigments contain also blue and yellow, which gives them a violet or orange tinge. This is a matter requiring very serious consideration in the mixing of pigments to obtain a given hue. For instance, if you wish to obtain a green, which is composed of blue and yellow only, you must be careful to mix together such pigments as contain no red, for if red be combined with blue and yellow a certain quantity of black is produced by the combination of the three primaries, which tarnishes the purity of the green. The same rule applies to the mixture of other coloured pigments. Theoretically, the union of the primary colours produces white, but the mixture of primary coloured pigments produces grey, owing to the impurity of the colours of the pigments.

The primary colours being three, the secondary colours are three also; two primaries go to form a secondary, and this secondary colour is complementary to the primary omitted from its composition, and *vice versa*. Thus blue and yellow form green, which is complementary to the omitted primary *red*, as red is complementary to green. We shall have to consider these complementaries hereafter, as they form a very important feature in the science of colouring. Although there is but one pure normal type of the three primary colours, there are many varieties of the secondary colours, green, orange, and violet which are also pure. These are *hues* depending upon the greater or lesser quantity of one of the primaries; thus blue and red will produce violet, purple, indigo, lavender, hyacinth, and other hues of violet, all equally pure, so long as yellow is kept out of the combination. Green revels in an infinite variety of hues, all equally pure. Orange being composed of two similar colours, is more limited in its range.

I do not speak of *tertiary* colours, as that word has no definite meaning. What is meant by those who speak of tertiary colours is simply the endless combination of the three primary colours in

unequal proportions, producing greys, or browns, when red predominates in the mixture.

We have now to consider the *tones* of a colour. Tone is the same as intensity; if you paint a panel with a mixture of normal grey, composed of pure black and white, commencing at one end with pure white, and gradually deepening in intensity until it reaches black at the opposite end of the panel, you will have all the tones of normal grey. If, when dry, you cover the grey with a coat of transparent colour, whether simple or compound, you will obtain all the *tones* of that colour, therefore we say that the tones of a colour consist of the modifications the pure pigment undergoes by the addition of white, which heightens its tone, and of black which lowers it.

Photographic Glossary.

Uranium—A metal obtained from *pitchblende*. It is usually obtained in the metallic state by decomposing the protochloride with sodium or potassium. In colour it is like nickel and iron, but soon tarnishes upon exposure to the air, becoming yellow. It dissolves with evolution of hydrogen in dilute acids, forming green solutions. It forms four compounds with oxygen. The specific gravity of uranium is 18.4.

Uranium, Oxides of—The combinations of uranium with oxygen are the protoxide, the sesquioxide, and two intermediate oxides, which may be regarded as compounds of the other two. *Protoxide of uranium* was for a long time mistaken for the metal itself: it appears in the form of a grey or brown earthy powder; sometimes in crystalline scales of a metallic lustre. *Sesquioxide of uranium* is used for imparting a delicate yellow hue to glass—the glass thus coloured is called *canary* glass, and completely intercepts the chemical rays of light.

Uranium, Nitrate of, is formed by the metal or either of its oxides with nitric acid. It crystallises in prisms of a lemon yellow colour. The solution of this salt possesses the power of lowering the refrangibility of rays of light which fall upon it, producing the peculiar phenomenon called *fluorescence*. Nitrate of uranium has been employed by M. Nièpce de Saint Victor, and by Mr. Burnett, as a substitute for nitrate of silver in the positive printing process.

Uranium Printing Process.—The paper used for taking the proofs must be kept several days in the dark previous to use, and handled with great care. It is floated on a bath composed of nitrate of uranium one ounce, distilled water five ounces, and then dried in a dark place. It will keep thus prepared for any length of time. To take a proof expose this paper under a negative from one to ten minutes in the sun, or from a quarter of an hour to an hour in diffused light, according to the intensity of the light. A faint impression only becomes visible, which is developed by floating the paper on a bath containing one ounce of nitrate of silver dissolved in a pint of distilled water, to which a drop of acetic acid is added. The image appears immediately. The proof is then washed in several waters. It may be immersed in the following bath, composed of water thirty-five ounces; chloride of gold thirty grains; hydrochloric acid two or three drops; this bath develops the picture more rapidly than the nitrate of silver. The prints become much more vigorous if dried at the fire. This is the original process proposed by M. Nièpce de Saint Victor: it is capable of receiving many modifications, most of which have been described in this Journal.

New Books.

Instructions for the Successful Practice of the Fothergill Dry Process; *also Remarks upon the Preservative Dry Processes Generally, &c.* By Alfred Keene, Chemist, 115, Warwick Street, Leamington.

This is one of the little pamphlets that one of our correspondents stigmatised, a short time back, as being "worth nothing, as it is to be had for nothing"—that is, to purchasers of a certain quantity of the collodion made and sold by the author.

We objected to the libel at the time, and in the present case we do so emphatically. It is not adapted to those who know nothing at all of photography, but gives very ample instructions to those acquainted with the working of ordinary moist collodion, and are desirous of mastering any of the dry processes; for though that known as Fothergill's obtains by far the largest share of notice, many, not to say most, of the details insisted on for working that satisfactorily are also more or less applicable to the others.

Mr. Keene has not confined himself to one rigid line of action, but has, in our opinion, acted most wisely in pointing out how, by strict adherence to the principle involved, much latitude in mode of manipulation may be allowed without interference with the results, and thus a considerable choice of routes is offered, all leading to the same goal.

We have also been favoured with a specimen stereograph of Warwick Castle, which gives a capital idea of that noble structure, and illustrates favourably the process advocated so strongly and so well by the pamphlet, which, by the way, we perceive, on again looking at it, is to be had for a small charge by those who are *not* purchasers of the collodion.

Foreign Correspondence.

Paris, October 12, 1859.

The return of the publishing season brings with it a fair instalment of photographic literature. Some four treatises, three of them new, and one a new edition, have already appeared, and more are promised anon. First among them is M. Chevalier's *brochure*, which is not a systematic treatise on heliography; but, like his previous publication, a collection of essays by various photographers, MM. de Brebisson, Civiale, Bacot, Adolphe Martin, Festeau, de Nostitz, and Baillieu d'Avrincourt, with notes by M. Nièpce de Saint Victor upon the colour of proofs, and two articles by M. Chevalier on photographic optics. The value of this work must be apparent, seeing that the component parts are contributed by skilled practical photographers. The next work is *L'Art du Photographie*, by M. de la Blanchère, whose reputation as a scientific photographer stands very high. His book is not an elementary treatise, but comprehends photography on paper and on glass, in which the formulæ producing the best results are given. The author has preferred to treat of the artistic and intellectual part of photography rather than of mere manipulation. The reader is presumed to be already familiar with the ordinary processes, and with sufficient knowledge of chemistry, to enable him to comprehend the philosophy of his proceedings. One merit the book possesses, which will render it invaluable to the photographer—everything in it is the fruit of the author's experience, clearly and conscientiously stated.

M. Robiquet has published his *Manuel Theorique et Pratique de Photographie*. This is an elementary work, containing numerous wood-cuts, illustrative of the chemistry of photography and of the various manipulations. The latter section occupies 107 pages. The third section comprehends the history and theory of photographic phenomena. M. D. Van Monckhoven has ready a new edition (the third) of his *Traité Général de Photographie*. The favour with which the former editions were received will doubtless be extended to the present. The author is well known as a scientific photographer, and has contributed many valuable essays to the perfection of the art. While writing this, yet another little *brochure* has been placed on my table, *Photographie Elémentarie*, by M. Georges Robert. It is intended as a first book for beginners, and treats of photography on glass and paper. I have not yet had time to examine it, but I do not expect that it will call for any lengthened notice.

M. Nièpce de Saint Victor has contrived another very ingenious and interesting chemical photometer. Into a wide-necked flask or bottle introduce a saturated solution of oxalic acid with some undissolved crystals resting on the bottom of the bottle. Into this solution throw a given quantity of a solution of nitrate of uranium, or simply of oxide of uranium. The bottle is hermetically closed by a cork, through which a straight graduated glass tube is passed through the liquid, and the upper portion of which rises a certain height above the cork. Thus arranged, if left in the dark, the bottle shows no particular phenomenon, the liquid in the tube remains at the same level as that in the bottle; but if it be exposed to diffused light, or to the direct light of the sun, the oxalic acid, under the influence of light, aided by the presence of the salt of uranium, is decomposed, with the formation of carbonic oxide, which rises in the flask, and pressing on the surface of the liquid, causes it to rise in the tube with a rapidity and abundance proportionate to the chemical intensity of the light. This simple little apparatus works remarkably well. It only remains to determine whether the proportion between the disengagement of the gas and the chemical intensity is perfectly established, and whether we can by this means accurately measure the quantity of the chemical action of light—whether it be diffused or solar at different hours of the day, and in various seasons and at various places—and if, in a word, this mixture suggested by M. Nièpce de Saint

Victor can wholly replace the sensitive gaseous mixture proposed by Messrs. Bunsen and Roscoe. The diameter of the tube, and the best mode of dividing it, must be ascertained by experiment.

In my letter of, the 10th ultimo I briefly described another photometer, under the name of the *solar pile*, invented also by M. Nièpce de Saint Victor. I am now enabled to supply a more detailed description. Through the cork of a wide-mouthed bottle we introduce two metallic plates, one of zinc the other of copper, to which are soldered two copper wires, and forming together a small simple pile. The liquid or mixture put into the bottle is the same as that of the preceding apparatus, a solution of oxalic acid and of nitrate of uranium. If we complete the circuit, even in the dark, an action commences with the evolution of a current which sensibly deflects the needle of the galvanometer. But if the bottle be exposed to the light, the action is much more energetic and vivid, and the quantity of carbonic oxide is very considerable. It may be seen to disengage itself under the form of smoke or transparent cloud. Up to a certain point the oxide or nitrate of uranium may be replaced by nitrate of perchloride of iron. J. P.

Correspondence.

HONOUR TO WHOM HONOUR IS DUE.

To the Editor.

Sir,—I find in the report of the meeting of the Chorlton Photographic Association it has been omitted to be mentioned that I was enabled to present the photographs through the kindness of Mr. Ebbage, from whose negatives they were printed. The insertion of this in your next will oblige.

I am, yours, &c.

ALFRED KEENE.

Leamington, Oct. 4, 1859.

WHITE POSITIVES ON GLASS.

To the Editor.

Sir,—Some time ago I sent you an account of my method of working in taking positives on glass, or rather of the materials that I was then using. I lately saw in your Journal a formula for a developing liquid, the principle of which appeared to be sound, although the formula itself, from a misprint of ounces for drachms, was impracticable. Before the correction was published, I had contrived the following modification as a means of carrying out the principle:—

1.	Protosulphate of iron	1 ounce.
	Dilute sulphuric acid (containing ten per cent. of oil of vitriol)	3 ounces.
	Water to make up to	16 „
2.	Spirit of wine	$1\frac{1}{2}$ „
	Water to make up to	16 „

When wanted, mix equal parts of these solutions. Separate they will keep in well-corked bottles for months: whether they will do so mixed I do not know; but I have never found it necessary to reject what has been mixed a week or two, provided the bottle has been corked.

This formula gives a good white not so sparkling as that produced by nitric acid, and therefore more pleasing to most persons. The proportions given answer very well; but I have not had time to try whether they may be varied with advantage. The spirit of wine may probably be reduced to one ounce without injury, its use being merely to cause the liquid to flow freely over the plate.

I am, yours &c.

G. JACKSON.

TONING—RE-DEVELOPING.

To the Editor.

Sir,—In the toning of prints with the alkaline chloride of gold I have been rather annoyed lately. The pictures have toned, to all appearance, very nicely; but, on adding the hypo', they turn red, and rather granulate, and frequently all the half-tones dissolve out. The toning I make with one grain chloride of gold, five ounces water, twenty grains carbonate of soda. Fixing—Hypo' one ounce, water five ounces. Sensitising—sixty grains nitrate of silver, water one ounce.

In the re-developing of negatives with pyrogallic acid, after using iron, I have had occasionally deep orange stains in various parts of the negative. The collodion contains bromide. If you could spare a few lines in the next number of your most useful work to help me out of these errors, I should feel obliged.—I am, yours, &c. M. A. H.

[The reddening in the hypo' shows that there has been *very little gold deposited;* perhaps your gold bath has been nearly exhausted. Have you noticed any deposit in your stock bottle, or was the bath freshly mixed? The fault, from whatever cause, is certainly insufficient deposit of gold. The granulation is most probably owing to the size (starch) being entirely removed from the paper by the strongly *alkaline* condition of the bath. We recommend you to try Maxwell Lyte's formula, in preference, for the toning bath.

The defect of orange-coloured stains, when re-developing, is due to the iron solution not being properly washed off before adding the pyrogallic acid and nitrate of silver. Wash and *drain slightly* several times between the two operations; the last washing, before using the pyrogallic acid, should be with distilled or rain water.

HINTS TO LEARNERS.

To the Editor.

Sir,—From the regular perusal of The Photographic Journal, I see that inquiries are often directed to you, asking your advice as to the purchase of apparatus, &c.; but your reply invariably is, that you cannot recommend any particular maker, lest in so doing you should be deemed partial. Of course, then you will not do so publicly.

But suppose you were yourself in want of a good lens, or you had a friend in a similar situation, there is no doubt but you would give your advice as to where he should go to procure one. If he had the means you would probably advise him to go to a first-class house, pay a first-class price, and obtain a first-class article. Perhaps you would say—go to Ross, Voigtlander, or some other of world-wide reputation. But to give £5 or £6 for a quarter-plate portrait combination, and double or treble that sum for a half-plate one, a *poor* amateur would consider paying too dearly for his whistle, when he can obtain *fair* articles at less than a quarter of the price.

I read with great interest and pleasure your report on Derogy's lenses, as not only giving the novice an insight into the features, qualities, &c., of lenses, but also useful advice for enabling him to procure a fair article at a moderate price. In that report you say that the lens examined by you was quite equal to any French one that you had hitherto tried.

I had in my short practice of the fascinating art been led to form a high opinion of Lerebour's lenses, but from your report it would seem that they have no superiority over those made by M. Derogy. I have tried a quarter plate of each of these makers, and though I am not able to state which was the better of the two, yet both of them were superior to one that I have in my possession, and with which I have always worked up to this time.

One of your correspondents, in acknowledging your kindness for the report on Derogy's lenses, asks where he might obtain a suitable camera that might be used with all its various arrangements. This is a question that took my attention, and it must strike every one that an ordinary camera will not do for all the combinations of which it is capable. It is evident that either three cameras at least will be required, or there must be one of great expansive properties.

Cameras are sometimes made of vulcanised india rubber, or some such material, which I believe would answer very well for all three portrait combinations. The price is two pounds or fifty shillings.

I possess a whole-plate camera to which I have adapted a half-plate lens. I took a piece of wood to the cooper's and had an aperture made of the size required, glued it to the inside of the front of the camera, and screwed the brass ring which receives the lens to the *inside* of the camera. I was then enabled to work with my whole-plate camera and half-plate lens. I should not forget to state that I was obliged to take out the pinion which works the combination: consequently I am obliged to focus by means of sliding the camera, or drawing out or pushing in the tube, which I do not find at all inconvenient.

As to plate frames I was sorely puzzled for a time; but taking two strips of deal, I cut out a groove on one side of each, put the strips of deal inside the dark slides, at about the distance of the breadth of the sensitive plate apart; then put the plate on the grooves, shut the door of the dark slide, and found the spring sufficient to hold the plate firmly in its position. The deal strips reach from the top to the bottom of the dark slide, resting on each end; and by sliding one to the right and the other to the left, I have what may be called an universal inner plate-frame, being adapted for all sizes, up to whole plate $8\frac{1}{2} \times 6\frac{1}{2}$.

I have various marks on the inside of the flap of the dark slide, to serve as a guide to putting the plate in the centre; and I have also corresponding marks on the focussing screen.

I can hardly suppose that there will be, *to you*, any thing new in the above: perhaps it may however be useful to some of your correspondents. But whether or not, I beg you to excuse the trouble I am giving you, and if you deem the remarks in any way useful you may use them as you think proper; at the same time, if you take no notice of them it cannot be an offence towards me.

Your remark about sliding fronts is very good. I think it would be very useful to have sliding fronts to every camera, which the amateur should make, or get made, for himself, and which he would do at a very trifling expense. Then, as you remark, he could have them all of one size, adapt-

able to each and all of his cameras. Such fronts would be very useful for testing lenses, especially such as Derogy's, with many combinations. The practitioner would then have nothing to do but to screw the brass ring to one of the sliding fronts: the lens would then be ready for any camera that he might have in his possession. Or by very little ingenuity he might use a lens occasionally without screwing to sliding front at all.

"Necessity" is said to be "the mother of invention;" and I am confident that amateurs in general might do much more for themselves than they are in the habit of doing if they would only try.

When I got one of Derogy's lenses for trial I hardly knew how it was to be attached to the cameras, for I did not at all like the idea of taking off the rings already on in order to attach Derogy's. In fact, I could not have done so, for the lens being one of the quarter-plate patent portrait combination, the aperture in the whole-plate camera was too large. So I again resorted to the cooper, got him to find me a piece of wood of the proper size (about $4\frac{1}{2} \times 6$), make an aperture through it of the required dimensions, which he did in a few minutes, charging me but threepence for it. I then adapted it to the cameras myself, being only the work of a few minutes more. I was thus enabled to take pictures with all the combinations, with one exception; for when using the lens for the smallest pictures with the portrait arrangement, my camera was not of sufficiently short range to obtain a focus. I have gone to a greater length than I intended, but for so doing I hope you will excuse me.—I am, yours &c.

Wakefield, October 5, 1859. A WOULD-BE PHOTOGRAPHER.

[It is not easy for those familiar with all the details of such an art as that of photography to know in what particular points novices are especially desirous of information; we therefore would gladly encourage the mutual interchange of correspondence in our columns, between those *in statu pupillaris*, if we may so term them. Although there is nothing *new* in the preceding letter, we have no doubt that it will be nevertheless very useful to many of our readers.—Ed.]

THE SOLAR CAMERA.

To the Editor.

Sir,—In perusing The Photographic Journal for the 1st and 15th ultimo, I think great credit is due to you for your able and candid assertions regarding *Woodward's Solar Camera:* it is by no means entitled to a *patent*.

It is now more than sixteen years since I assisted Messrs. Adamson and Hill, photographers, *Edinburgh*, in taking a few copies of magnified representations of minute objects by an achromatic solar microscope, which I had made for Mr. Octavius David Hill, Calton Stairs, Edinburgh. (At that time the calotype paper was employed, and of course the outline was not so well defined as with collodion on glass, the latter process not being then known). The objects I adopted were transvex sections of wood, about three-eighths of an *inch* in diameter. The enlarged copies or impressions taken were, so far as I recollect, about eighteen *inches* in diameter. The last time I saw the aforesaid magnified impressions, they were framed and hanging in Mr. James Bryson's shop, Princes Street, Edinburgh; and, as regards patents, Mr. Hill and Mr. Adamson had arranged to lodge a *caveat*, but the premature and lamented death of the latter prevented it.

Messrs. A. and H. already alluded to, had also a camera, about two feet square, fitted-up for taking portraits as large as life; but the imperfections in, and difficulty of, preparing paper so large were against it.

I also made a speculum, of twenty-four inches diameter and thirty inches focus, for the aforesaid, for taking smaller portraits, or to reflect light on the object; but that was never much used.

Next, in your Journal of the 15th ultimo, page 225, you write on "*Photographs of Microscopical Objects*." They are very beautiful and interesting. I have a brother here who has taken hundreds of them with the solar microscope, the greater part of the objects being sections of wood such as you recommend.

You speak of a parabolic or spherical mirror receiving incident rays at an angle of 45° (page 224, Sept. 15). This will never do, because the angle of incidence must be equal to the angle of reflection. Parallel rays, falling incident on a plane mirror at the same angle of incidence, undergo the same angle of reflection; but let the same rays fall on a concave mirror, then the central ray would be incident at an angle of 45°, while those on each side would fall at greater and less angles, and be reflected, giving a very distorted elliptical image, whatever lenses it may be refracted through afterwards.

I am perfectly aware of your capabilities as regards the theory of optics, only your mind must have been otherwise engaged at the time you wrote.

Trusting you will excuse my presumption,

I am yours, &c.

Newcastle, Oct. 6, 1859. THOMAS DAVIDSON.

[Our correspondent has misunderstood somewhat the article to which he has alluded.—He will perhaps perceive by the article in the present number what our meaning is.

We are quite aware of the aberration existing when reflection occurs from a spherical mirror; *but as this is precisely what occurs in a compound achromatic microscope*, in which the *ratio* of enlargement is greater far than would be required photographically, we are convinced that our plan would be practicable and advantageous.

We should not employ anything like such a proportion as twenty-four inches diameter and thirty inches focus, but with such diameters have the focus six feet at least. It must be borne in mind that we do *not require* an image of the source of light for illuminating, and useless rays can be cut off by a diaphragm.—Ed.]

ANSWERS TO CORRESPONDENTS.

G. T.—Pyrogallic acid 1 grain, distilled water $6\frac{1}{2}$ drachms, Beaufoy's acetic acid $1\frac{1}{2}$ drachms.

Papier Moure is not a photographic chemical, although you might have seen it at photographic chemists'.

In Memoriam.—The late Mr. Arthur Heufrey *was* the first Editor of the *Journal of the Photographic Society*.

Smellfungus.—The best disinfectant for the annoyance you describe is a solution of nitrate of lead.

Chemicus.—Sulphuric acid can be obtained economically from sulphate of lime by Mr. Shanks's process.

Walter S.—Silver is generally found in sea-water when sought for in analysis.

C. J. L.—The ounce of 480 grains is no doubt the one meant. How else would it make a forty-grain solution?

Sea-View.—The stereographs named are by Mr. Samuel Fry, of Brighton, See advertisements.

Thos. Price.—1. See the letter of Geo. Jackson in the present number. 2. Add alcohol till it flows.

A Would-be Photographer—*(Great Marlow)*.—Get Hardwich's "Photographic Chemistry." You will find it contains the *best* information that is to be had on the subject.

H. Walter.—After pouring off the varnish hold it before the fire, as well as having the plate warm beforehand. Our nerves are not so easily affected, especially by the *gun* you mention.

David.—You cannot legally sell the negative without permission of the owner of the copyright. The better your negative the less likely is it that you will obtain the permission.

Louisa A.—If you will read the advertisement by the light of common sense, you will soon perceive that, like so many others of the same sort, it promises an impossibility in return for twenty-four postage stamps!

Barnaby Rudge.—The French unit of measures of length, occupying the place of our yard, is the *mètre*, which measures 39.37 inches. It is the length of a pendulum vibrating seconds in the meridian of Paris.

H. Morton (Cambridge).—In water, at a temperature of about 54°, bromide of potassium dissolves in the proportion of 63 grains in 100 grains of water.

A. Mackae (Greenock).—If you prefer to make your own iodising solution, you will find the salts of cadmium preferable for your particular purpose to the salts of potassium or ammonium.

Augusta.—Such an outfit as you desire may be obtained for about Five Pounds. Any respectable dealer will "put up" what you require if you state your wishes clearly in writing.

J. Ford (Boston).—Carbolic acid, phenic acid, phenic alcohol, hydrate of phenyl, are but different names for the same substance. We are not surprised at your perplexity. You will find a paper on the employment of oxyphenic acid in photography on page 225 (Sept. 15th).

A Wanderer.—A treatise, of the kind you need, has not yet been published, but we learn that such an one is in a publisher's hands: it will treat photography in *all* its bearings, chemical, historical, artistical, optical, and manipulatory.

Pyro.—Fahrenheit's scale is always understood, unless otherwise expressed. As a general rule, and to remove all doubt, it is better to place F. or C. after the figures, to indicate either Fahrenheit or Centigrade.

Bandon.—Amateur.—Hy. Robertson.—B. L.—Ignotus.—Most of your inquiries will have been answered in our article on the solar camera in the present number. The tube used by the first does not allow the oblique rays to act. You may employ your portrait combination in lieu of an orthographic one; but if so, insert a diaphragm with about one-and-a-half inches of aperture between the front and back glasses. *B. L.* must give more time when he enlarges to six diameters than when he is content with four. *Ignotus* will not find an ordinary landscape lens do very well: it is too slow.

Chas. Mooreland.—The reason why one of the lenses of the given focal length and equal diameter is better than the rest in rapidity of action, and sharpness of definition, is evident enough. It is not the quality of the glass (though that might influence the result to some little extent), but the *spherical aberration* is better corrected: hence the lens will, as you have found, be deficient in what is called *depth of focus*. We regard this deficiency! as a positive advantage. Depth of focus with a large aperture is all nonsense. If you require this quality, obtain it by contracting the aperture. A good lens will even then work as quickly as one with a large aperture, possessing the so-called depth of focus.

Received.—Archd. Burns: Due notice in our next.

All Advertisements *and* Letters *on the* Business *of this* Journal, *should be addressed to the* Publisher, 32, *Castle Street, Liverpool.*

THE PHOTOGRAPHIC JOURNAL.

No. 105, Vol. VI.—NOVEMBER 1, 1859.

It certainly does appear to be a most extraordinary circumstance that M. Niepce de St. Victor should again have discovered a very ingenious ACTINOMETER that was very unreasonably originally contrived by Mr. Burnett, and published in our pages something like *ten months back*. The letter of our Paris correspondent, which we published in our last number, contains a description of the learned Frenchman's new (?) arrangement: will our readers kindly re-peruse the same, and then refer back to the number published on 15th December, 1858, page 319, where they will find precisely the same idea, not merely as a crude suggestion, but even more elaborately worked out by Mr. Burnett than M. St. Victor appears to have thought necessary.

Now that this subject appears to be drawing more and more attention—and deservedly so, for it is one of vast importance—and that the paper alluded to was published in our last volume, since which time the number of our readers has very greatly increased, we may be excused for reproducing that part of the paper which more immediately bears upon the point in question: we therefore give it *verbatim*,

Professor Draper, in America, has already recorded very interesting observations on the variation in spectral position of the erythroactinic influence; but we want continuous and connected series, such as can only be obtained by the employment of a set of *self-registering* apparatus in every public observatory, and in every other locality wherever an honest and not absolutely stupid person (for the attention required would be of the simplest kind) can be got to look after it.

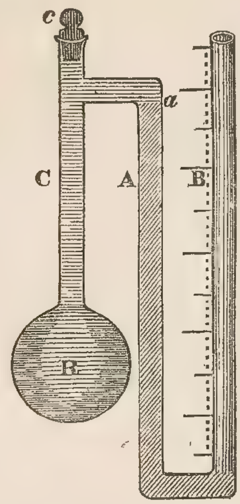
Where sensitive *paper* is used, either by itself for the registry of the strength of cyano-actinism, or as the means of recording the indications of thermometers (either of the ordinary kind or electrothermic), or of recording the indications of fluid actinometers, the uranic and ferric papers offer considerable advantages from the length of time during which they retain their sensitiveness unimpaired, much greater than that of similarly sensitive argentine papers.

In the fluid actinometers, the solutions of uranic-oxalate, ferric-oxalate, and the mixture spoken of by Mr. Fowler, at the late meeting of the British Association, and many others,* might be employed, but the *measurement ought to be made by aid of a column of mercury* connected with the bulb or other reservoir of the sensitive fluid, thus—The tube A should be filled with mercury to the point *a*, when we commence, the mercury being poured on at the upper end of the tube B, and forced back by a rod and piston made to fit it. The sensitive fluid, oxalate of uranic oxide or other, is then introduced (of measured strength) at a small opening left at Cc, and when it has filled the space left vacant by the mercury, a glass or gutta percha stopper is placed in and closes the opening. It may probably be found advisable to fill only the reservoir R, or part of it, and to leave the air in the tube C. This tube C may be of any length, and twisted in any direction for our convenience in placing the reservoir. The tube may be protected from the light by paint or red paper, and we may regulate the action, by leaving as much or as little of the surface of the reservoir uncovered as we find to be convenient.

For registering by this apparatus a sheet of sensitive paper, of the same length as the tube *b*, is made to roll off regularly so as to pass behind it, all the surface of the paper being covered up *except where it passes behind a narrow slit which is exactly closed by the tube B*. The light will thus obviously register the height of the mercury at each instant of the day on this sheet, and the diagonal line, which a uniform actinism ought to describe on the sheet, whether a straight or a curved one, in consequence of the diminution of the quantity of decomposable chemical in solution as it becomes gradually exhausted, being once ascertained, any deviation from it, upwards or downwards, will at once indicate, and be the measure of corresponding difference in actinic intensity.

* I do not say that those would all furnish the same standard however adjusted as to relative strength of solutions, different chemicals being affected in different proportions by different parts of the spectrum; though in the case of the uranic and ferric salts, the oxygen being probably the body allotropized in both, it is not improbable that the proportionate relation to different parts of the spectrum might be found to be identical. But if we find different sensitives differently affected, this only enlarges the field of observation, and offers the opportunity for the collection of *additional* and *most valuable data*.

I need hardly mention, as it must be sufficiently evident to any one possessing the slightest acquaintance with the principles of physics, that the tubes A and B must occupy a *horizontal position, side by side*, and not an upright one, when the actinometer is at work, otherwise the increasing pressure of the column of mercury forced into the tube B would make the indications given on the scale, by equal disengagements of gas, become gradually less and less.



The rough sketch is intended to give the principle only, not the form, and I have given only one mode of employing it. Another would be, to have a large number of them ready filled and in order, and then, by machinery or by hand, uncover one—say every hour, or every half hour, or ten minutes, during the day, and then record the rise of the mercury during a given fixed period of its exposure. All this may be done and registered by machinery; and it is very desirable that we should have similar registers, placed both in undecomposed sunshine, in diffused light, and in different parts of the spectrum, either prism-refracted or transmitted by different permeable media.

It will be at once seen from the preceding, not only that *oxalate of uranium* has been already employed for measuring the actinic force by confinement in a flask, but that a convenient special apparatus has also been contrived, by which the question proposed by our Paris correspondent, viz., "whether the proportion between the disengagement of the gas and the chemical intensity is perfectly established?" can be readily put to the test. We have sent him a copy of our former number. We shall be curious to know by what piece of ingenuity he will endeavour to extricate his compatriot from the dilemma in which he has placed him.

It has just occurred to us that the Abbé Moigno brought forward the same experiments at the British Association Meeting, and on reference to our report we find that such is the case, though the circumstance did not strike us at the time we were correcting the proof.

A Correspondent once accused us of "fulminating anathemas;" we have one to iterate upon the present occasion, called forth by an abuse of the patent nuisance. In the last number of the

Journal of the Photographic Society, at page 57, may be found a *Description of the New Patent Stereoscope*, the name of the author or patentee being prudently withheld — a precaution at which we certainly rejoice, inasmuch as we can make our comments undeterred by any fear of being guilty of offensive personalities.

Some ingenious gentleman appears to have discovered that many architectural subjects must be taken by "cocking up" the camera, or not taken at all; and that, when so treated, lines that should be parallel are rendered converging. In order to render such stereographs available without the observer being annoyed by the distortion, the same ingenious patentee has made the novel (!) discovery that they should be viewed in the stereoscope in a position *inclined to the observer*. Had he contented himself with announcing his discovery (!) no one would have cared about the matter — everybody is not bound to know even the most simple facts; but when such an one is foolish enough to waste his money in taking out letters patent for a stereoscope that shall permit of the stereographs being presented to the eye in an inclined position, he is not likely to meet with much sympathy for the loss of his money at all events. Our readers may think we are joking: we quote the concluding words of the article.

"The patent includes the application of the above principles to the stereoscope in whatever manner the print may be presented to the eye in an inclined position."

M. CHAS. CHEVALLIER, the well-known French optician, has recently published a new edition of his *Manual of Photography*, in which there is a passage that struck us as exquisitely comical. After describing the *modus operandi* adopted by a Russian photographer in practising the collodion process—the description appearing in the form of a letter from the Russian nobleman, who states that he has frequently operated at a temperature of 48° Reaumur (about 140° Fahr.) — the editor remarks: — "This observation is not without interest, demonstrating as it does *that collodion may be employed in hot countries*." The *naïveté* of this announcement is certainly amusing, after the experience of Roger Fenton and Robertson in the Crimea, and Frank Frith in Egypt and Nubia. We have heard Mr. Fenton state that in the Crimea the heat was at times so great that a funnel of gutta percha which he kept in his photographic van became so soft as to *slip through the hole* in a piece of wood in which it was usually kept; and when Mr. Frith was in Egypt, it was not an uncommon thing for the *collodion to boil* when poured upon the glass plate.

THE last number of the Journal of the Photographic Society contains a communication of some interest from the Rev. T. M. Raven, one of the prize-winners at the last exhibition of photography held in Edinburgh, under the auspices of the Photographic Society of Scotland. While printing some proofs in *bright* and *warm* weather, a piece of cardboard being placed between the back of the pressure-frame and the sensitive paper, on one print being sufficiently exposed, which happened in a short space of time, he *immediately* changed the negative for another, placing also a fresh sheet of sensitive paper, and replacing the piece of cardboard as before. *On to the back of the sensitive paper was almost immediately transferred the impress of the negative that had been removed from the frame*, while the opposite side of the same sheet of paper was at the same time receiving an impression from the negative with which it was then in contact. This we remember was brought under notice at the meeting at Aberdeen by Professor George Wilson; but the report which we received of the fact was too vague and incomprehensible for us to notice in our impression of the 1st ultimo.

The rev. gentleman states that the "cardboard and sensitive papers were perfectly dry," and ventures a supposition that the effect is attributable to "the combined influence of heat with light." Now, without for one moment questioning the good faith of the statement relative to the *perfect dryness* of the paper, &c., we certainly doubt the correctness of the assertion in a strict sense; and for this reason, that it is not probable that any one would voluntarily employ paper *perfectly dry* for printing upon photographically, unless he had some special object in so doing, because it not only would entail additional trouble in bringing it to that condition, but would be highly inconvenient to operate with. Few persons but those who have tried the experiment are aware of the hygroscopic properties of paper, and would be astonished to find for how short a time paper *perfectly dry* will remain so. We have no doubt that the paper and cardboard were what is conventionally termed "dry;" but this is very far indeed from a total absence of moisture.

Under any circumstances the fact mentioned is interesting, but we do not consider that *light* plays any part in the phenomenon.

In the same communication already adverted to is another interesting point, which we quote as follows:—

> An experiment I have been making with sensitive paper for the waxed-paper process has struck me as curious, as I have been under the impression that the iodide of silver in the paper could be rendered soluble by immersing it in a rather strong solution of iodide of potassium. I prepared, a few days since, several sheets of paper for the camera which the weather prevented me from using; I immersed in a bath of iodide of potassium (12 grains to the ounce), and left them covered up, excluded from the light, for three or four days, after which I hung them up to dry in a very dark room; the following day I exposed pieces of these papers to light, when they gradually changed colour, and in the course of two or three hours became a dark brown.

This last is a circumstance at which we are by no means surprised. We find in the Fothergill or Taupenot processes that all the free nitrate of silver may be converted into an analogous salt of the chloride *without destroying the sensitiveness*, and this we believe to be owing to the fact that a combination between the organic matter and the nitrate of silver has been previously accomplished, which combination is not destroyed by the action of the chloride, and which also plays a part with regard thereto that is at other times performed by the free nitrate of silver. In the case of waxed-paper precisely the same conditions may be in force.

With regard to the solubility of the iodide of silver in a strong solution of iodide of potassium we have to remark, firstly, that one of twelve grains to the ounce of water would scarcely come under this category; and secondly, that if even a saturated solution had been employed, it would not have removed the *whole* of the iodide of silver, as the small quantity of solution remaining on or in the paper would itself have contained some of this salt, while any attempt to wash the paper in water would have only resulted in re-precipitating the iodide of silver, by weakening the strength of the iodide of potassium solution.

While we regard the record of this fact as equally interesting and useful with the preceding, we cannot assent to the notion of there being anything mysterious or inexplicable therein.

IN the communications with which we have recently been favoured by Dr. Maddox, it may be noticed that his original experiments commenced with *paraffine oil*, as a means of rendering the paper transparent, instead of employing the troublesome process of waxing, though subsequently he used it as a vehicle for dissolving vegetable and animal wax, as well as availing himself of other solvents for a similar purpose.

We remarked, in connection with the first or second paper, that the samples prepared with paraffine oil appeared more transparent than those treated with belmontine, which Dr. Maddox imagined to be the same material in a purer state. We also mentioned a fact in reference to the respective qualities of these two substances as combustible bodies which led us to infer that, though allied, they were certainly different. We are

fond of collecting scraps of information from all available sources, and here follows one that we have hit upon relative to one of the substances named.

An inquiry has recently been instituted into the source of an accidental fire that occurred lately in Bucklersbury, on the premises occupied by the Patent Paraffine Light Company.

Dr. Letheby deposed he had analysed a bottle of paraffine oil. On March 13 he received from Mr. Stuchbury a sample of paraffine oil, which he had submitted to examination. He found it to be oil obtained by the destruction of the bituminous coal or shale. It was lighter than water, and gave off vapour at various temperatures, causing a peculiar smell. The vapour was inflammable at 140 degrees, and burned freely from a wick, or open saucer, at 160 degrees; by distillation it yields a very volatile oil indeed, the proportion of which is about one-fifth of the whole liquid. It was this volatile oil that gave the odour to the paraffine oil, and was the cause of its inflammability at low temperature. The other portions of the oil were of a more fixed character, and did not inflame or give off vapour under a temperature of 300 degrees. The vapour of the light volatile oil, when mixed with air, formed a very explosive compound. Its vapours were very inflammable in warm weather, especially in summer; and from the oil *not drying* like ordinary spirits, *but remaining fixed* on any absorbent matter upon which it falls, it was very liable to combustion from the falling of a lighted match.

Dr. R. D. Thompson, lecturer on chemistry at St. Thomas's Hospital, deposed—This oil could not be set on fire by a lighted match at the usual temperature. He agreed with Dr. Letheby as to the temperature at which it would ignite. According to his experiments it would not give off an inflammable vapour at the temperature of the day. He found gin boil at 190. At a temperature between 80 or 85 it was inflammable. He found with paraffine he had to heat it up to 130 degrees before ignition. He had extracted six or seven oils from it, but not volatile. The volatile part was exceedingly small in comparison to the others.

We presume that it will be conceded from the evidence given that paraffine oil contains a large proportion that is *not volatile*. We have recently been using belmontine for artificial illumination, and have several times had some spilt upon carpets, &c., but without any apparent detriment, as the whole seems to evaporate readily. This fully accounts for the superior transparency of paper treated with paraffine oil, while at the same time it points to belmontine as being probably a better medium for use as a solvent of wax, while it is much less obnoxious on account of its scent; for though it partakes somewhat of the same kind of odour, it is not nearly so offensive.

NOTICES OF RECENTLY PUBLISHED STEREOGRAPHS.

It is not often that we experience a greater amount of pleasure in examining any number of stereographic productions than has fallen to our lot lately, in studying a series of a dozen with which we have been favoured by Mr. Archibald Burns, of Edinburgh. Not only are they "got up" in the best style, but the printing and general manipulation leave scarcely anything to be desired, while the subjects chosen and the points of view selected are eminently good. The negatives, we are informed, have been taken by the Fothergill process, and if regarded as specimens of its capabilites they must be admitted as incontestible evidence in its favour. The intensity combined with transparency of the deepest shadows, the integrity of the high lights, and the delicate gradation of tone, ranging over every possible variation between the two, are beyond all praise, and the samples before us illustrate most happily several points of considerable interest to those in search of a dry process for adoption. Specimens of architecture, crowds of dwellings, distant hills, rugged rocks, expansive prospects, are all delineated with the most accurate fidelity. In one point alone do we think there is much room for improvement, and that is not connected with either the process or the manipulation, but with the character of the sensitive film:—the foliage, though fully impressed, exhibiting every detail, is unproportionally dark in colour compared with the rest of the subject, rendering one or two of them a little sombre in aspect. We think that by the addition of a little bromide of some kind to the iodising material the slight drawback we have indicated would be obviated.

Having pronouced judgment upon them as a whole we now proceed to deal with them in detail, and first we notice two specimens illustrative of the

Architecture of Edinburgh, viz., the *ancient* and the *modern*, the first of course being the more picturesque and interesting, represents a very characteristic portion of the *Old Town*, the view being taken from a corner where two streets unite, and exhibiting a portion of both—the post of honour being occupied by R. Turner's woollen rag store, and a horse standing with a laden waggon in the foreground. The old houses, with their quaint gable ends and varied storeys, each one projecting beyond that underneath and piled upon one another like Pelion upon Ossa, convey a capital idea of the locality. We venture to predict much popularity for this slide, and would suggest as a companion picture a view of the old Tolbooth. The illustration of the *modern* architecture is a portion of a building (not named) in the Roman style. We fancy this is the entrance to the Post Office. Though not so interesting as the preceding one it is equally well executed, the utmost amount of detail being combined with breadth of effect. Although no figures are visible, a couple of trucks, one of them containing builders' materials, are so disposed in the foreground as to hint at the existence of active life: this is in our opinion a good stroke of policy.

Holyrood Palace—A general view, taken as we judge from somewhere near the Calton Hill, is very effective. The palace itself, the ruined chapel, and the formal garden in the foreground, are backed up by a portion of Salisbury Crags, with Arthur's Seat towering above the whole. It gives an excellent notion of the spot.

The Burns' Monument, near the Calton Hill, is taken with the same background as the preceding and is very effectively rendered, the point of view being happily chosen, and the beautifully transparent shadows very artistic and telling. As an illustration of the capabilities of the process employed in taking the negative this slide is a favourable example.

Melrose Abbey—Of these ruins (which by the way are in capital preservation) there are two slides, both well executed, the characteristic effect of the masonry being admirably preserved. These will be highly valued both by architects and antiquaries.

Elgin Cathedral is a highly picturesque ruin; the general view is taken from a position which allows full effect to be given to the appearance of desolation. This slide is beautifully executed and the subject interesting. A second slide, illustrative of the same locality, is scarcely to be surpassed, whether regarded as a stereograph, a picture, or a specimen of photography. It is a view of the principal entrance, a pointed arch with its many mouldings, casting those rich shadows for which the ancient Gothic style is unrivalled. It is pierced with double pointed doorways, through which the interior is visible. The crumbling carved work of the heavy mouldings, and the general state of dilapidation everywhere painfully visible, tells but too plainly that the "light of other days is faded." This subject would be a fine study for an artist.

Roslin Chapel is a fine specimen of ancient architecture in a state of preservation, and contrasts admirably with the preceding, although the antiquary and architect will delight in it equally. The artist may object that the vew is formal; and so it is, but for all that the slide is a *perfect gem:* as a stereograph it cannot be surpassed. In the centre is an open doorway, which shows the depth beyond in spite of gloom, while above, three windows are visible, in which the effect of the ancient *quarried* glass is rendered with a perfection absolutely unique. The windows on the further side of the building are seen through those in the front, but at the same time the light is reflected from the surfaces of the panes with a truthfulness that, by any other means than by the aid of photography, is utterly and thoroughly inimitable.

Inverness from the Royal Observatory is quite in a different style. The winding river, spanned by a suspension bridge, the clustering dwellings, with here and there a "heaven-directed spire," the "eternal hills," in the far-away distance, with a castle-like building in the immediate foreground, combine to form a very picturesque whole. There is one drawback to this otherwise fine slide: it shows signs of having been produced with very short exposure (for we notice a tiny figure on the river's bank, and indications of clouds in the sky), and there is an extra degree of sombreness in the few trees visible, some of which are located rather unfortunately near to the spectator. In spite of this defect, however, the slide is a capital one.

On the Island of Inchkeith a portion of the inhospitable shore is reproduced with startling fidelity. This is a wonderful example of the application of photography to the purpose of geological illustration. The curious rocks of laminated structure, heaped together in wild and picturesque confusion, are given with marvellous accuracy of detail—the waters of the ocean being just visble in the extreme left corner of the picture. It is curious, highly interesting, and beautiful.

Nameless is the designation of a slide that presents a puzzling aspect to the beholder until assisted by the stereoscope, when it

stands revealed as a mass of lichen-covered rocks that Hunt would rejoice in as a study for his magic pencil. The grotesque and weathered rocks, some clothed with moss and lichen, are mingled with various other productions of the vegetable kingdom — here a flower, there the deeply-serrated leaves of a graceful herbaceous plant are seen; a few straggling bare stems are balanced by some downy leaves of a felt-like smoothness, and in the foreground a plant of dandelion, with its feathery tuft of seed ready to be wafted in all directions. This last is the only weak point in the slide: owing to the delicate nature of the feathery adjunct it trembles in the gentlest breath of air, and thus, though perfectly recognisable, it presents a slightly thickened appearance, which certainly deteriorates a little from its beauty.

We have dwelt at considerable length on these finely-executed and charming specimens, for we are persuaded that it would be impossible for the most undemonstrative lover of the beautiful to behold them without expressing admiration. In advising our readers to procure copies for themselves, we feel that we are putting them in the way of obtaining a treat for which we shall earn their gratitude. We do not hesitate to affirm that the specimens before us would materially enhance the value of any collection of stereographs in existence.

TRUTH IN ART ILLUSTRATED BY PHOTOGRAPHY.

By H. L. Keens, Sen.

[Read at the Meeting of the South London Photographic Society, October 20, 1859.]

After defining his meaning in the use of such terms as "art, nature, pre-Raphaelism, and photography," Mr. Keens said :—

In a court of law we are required to speak "the truth, the whole truth, and nothing but the truth;" so also in the art of painting is the same quality in all its bearings rigidly required. We will therefore direct our particular attention to this point while we endeavour to elucidate it.

We will suppose, by way of example, that an artist passing through the streets of our densely populated city has his attention arrested by the sight of a decrepid old man, apparently sick, and suffering acutely from hunger and neglect, endeavouring by the aid of a stick to drag his wasted form to some place of public observation, in the fond hope that some merciful creature may relieve him.

A young and beautiful lady, who has just stepped from the door of her home in a more public thoroughfare, has her eye attracted and her heart touched by the sight of so much accumulated misery: she stops and hastens to succour him. Now the artist who can, by a few simple materials, develop on his canvas a faithful representation of this interesting scene *in all its truthfulness*, would be deservedly worthy of our warmest gratitude. We should not be satisfied to see the beggar represented with a fine pink complexion, white linen, and smooth hair. No, let it be truthful; let him be shown with his dirty sallow skin, his hollow sunken eye, grisly beard, and ragged clothes: in short, all that which would naturally have excited the compassion of the young lady.

Her dress also, whether silk or satin, must be faithfully depicted, and with no less care than her graceful form and beauteous face; but, above all, the angel of compassion must speak eloquently from her melting eye, her expressive lip, and glowing complexion. This will serve to illustrate our view of *truth in art*. Let us now proceed to the subject of pre-Raphaelism.

Most of the pictures painted some centuries previous to Raphael were religious, executed either for churches or private oratories. The subjects were frequently single figures, representing our Lord, the apostles, or some of their successors who had signalised themselves in ecclesiastical history. In most of these subjects there have been more or less of the traditional types which artists then copied: thus, for instance, the representations of Saints Peter and Paul even now used correspond with the description given by the historian Eusebius.

In order to convey the religious feeling which the artists themselves were in possession of, they had recourse to the study of that general placidity and composure which were more or less stamped on the countenances of the ascetic and recluse of their times; consequently, so far as regards the expression of the countenance, their productions were truthful, but in every other respect they were generally untruthful.

But artists were occasionally starting up from their fellows and aiming at some nearer resemblance to nature, thinking their art was not advancing to its true goal while nothing was attempted beyond the representation, or rather communication, of some thought which, although in itself grand, pathetic, or beautiful, was but imperfectly conveyed.

As the technicalities of painting became more understood, they saw with pain and dissatisfaction that the solemnity of the subject was destroyed by shocking departures from the realities of nature, as in some pictures by Fra Angelica, in which the heads are worthy the study of a modern master, while the bodies of the same figures would excite the ridicule of the youngest tyro in the academy.

Nature *then* became the entire and exclusive study of the artist; and although it is to be lamented that the mind was so exclusively directed to a close imitation of the object as sometimes to commit itself to subjects unworthy of the pencil, while the noble and instructive themes of history or religion were laid aside; still it is satisfactory to know, that on the walls of the Vatican, Raphael portrayed forms and expressions (with some degree of excellence in colour and *chiaroscuro*) which satisfy the most critical, speaking to the heart and understanding of millions of the unlettered more powerfully than the most eloquent oration, and to the learned afford subject of reflection, developing new charms on every fresh inspection, like the oft-read poem, ever living, ever new. *And thus did truth in art extinguish pre-Raphaelism.*

Now let us imagine a traveller, who on entering a forest, finds several pathways before him, he feels utterly at a loss to know which will lead him to his place of destination, and he has reason to fear the terrible dangers attendant on the approaching night; a Will-o'-the-Wisp too has just risen, which will assuredly lead him into some marsh or bog, and no friend is near to direct his steps. Such was the position of the human mind in this country with regard to Art not many years ago; uncertain what course of study to pursue; at a loss to know whether Nature should be imitated, or the conventionalisms of fashion and fancy. One class of artists proposed the study of the Antique, another, that termed the Ideal, a third the indiscriminating imitation of Nature, while others chose a close adherence to this or that favourite master of some peculiar school or age. So unsettled was the mind of some patrons, owing to the conflicting styles and theories, that, from our own experience, many artists lost their commissions or employment. Pre-Raphaelism seemed to be the Will-o'-the-Wisp that had led astray art producers, art critics, and art patrons; when, like an angel from heaven to the benighted traveller, Photography appeared, and with a soft whisper pointed out the path which would lead us to that perfection in art we desired. To show this will be our object in the remaining portion of this paper. We shall consider it under three points:—first as to outline, second as to light and shade, third as to texture.

First, as to outline—The outlines in a good photograph are so true, that they will alone convey the most striking likensss of a face, with the precise expression of the sitter. Let an artist take a very light photographic print, and strengthen very carefully the outlines only, he will be surprised at the result. How many artists attempting to draw a face in outline, and finding themslves unequal to the task, have thrown aside the crayon and taken up the brush, hoping to succeed with shade and colour, and thus prodnced, in too many instances, an amalgamation of errors, which but scarcely pleased the ignorant and greatly disgusted the more informed. Observe the outlines in cloth drapery, how elegantly each line curves!—no disagreeable angles—no formal stiffness—all is ease and freedom. In the foreshortenings the folds appear multiplied, and to press upon each other, yet every line is clear, nothing confused, and each division and intersection worthy of study and imitation. In silk the crispness of the material breaks the lines by repeated cross-curtings and intersections; yet, notwithstanding, every break is but an introduction of smaller curves equally beautiful.

Light and shade — or, as we artists term it, *chiaroscuro* — is seen in perfection in a good photograph, whether we refer to its parts or to the whole. Observe the shadow under the nose: it is not an opaque patch of black, but an imperceptible gradation from the deep markings of the nostrils to the half-tint in which it becomes lost, showing the powerful effect of reflected light, which is also very manifest under the brows, on the lower part of the chin, nose, &c., and in general on the shadowed side of the face; but we must particularly admire the gentle gradation from the high lights to the half-tints, and thence again into the shade, until all is lost in the deepest recesses, and that so imperceptibly that there appears to be no shadow, and yet all is in full relief.

The old masters were delighted to study nature as reflected in a mirror, and learn thereby to imitate its mimicry; but could they have seen a photograph, an image fixed, that can be analysed, examined and studied, not like that in the mirror, fleeting and changeful as Nature herself, they would have been far more delighted, and as ready to profit by its suggestions as they did from those of the mirror.

How different from a good photograph are those disagreeable patches of light and colour, called pictures, which have of late so frequently disgraced the walls of our Exhibition, in which each object appears to be cut out of pasteboard and pasted on the canvas, not unlike some of those old drawings occasionally to be met with, representing playing-cards laid flat, and partially covering each other! No wonder that foreigners should have smiled with contemptuous surprise at such foolish productions.

Landscapes are beautifully portrayed by the photographic art; there is no mistaking distance in its productions although unaided by colour. Each tree in an avenue recedes from the nearer one; first, second, and third distances keep their respective places, until the extreme distance is lost in atmosphere, while the detail of the foreground is wondrous with leaf, moss, and bark in perfection. Unlike pictures of the new school, no distant hill or dark cloud in the horizon is ever there seen attaching itself to the head of some miserable figure in the foreground.

We should conclude with a few words on the subject of Texture, but that it is superfluous. Let any one examine carefully a good photograph, all is perfection — flesh, hair, silk, satin, velvet, cloth, lace, in a word, the exact texture of every object in nature, nay, it is — *Nature itself.*

> And who can paint like Nature?
> Can imagination boast such varied hues?
> And can she mix and blend them with such skill,
> And lose them in each other?

REPORT ON THE EFFECT OF CITRATE AND ARSENITE OF SODA WITH REFERENCE TO COLLODIO-ALBUMENISED PLATES.

By Alfred Rosling.

I have now tried the keeping properties of Taupenot's plates, as follows: — 1st, plain; 2nd, treated with a citrate of soda bath; 3rd, with an arsenite of soda bath, say to the extent of twenty-five days.

That is, on the 26th ultimo I excited six plates (stereoscopic) which had been previously prepared exactly alike: two plates excited as usual, two plates immersed, after exciting and washing in a bath (two grains to the ounce of rain water) of citrate of soda, and two plates in one of arsenite of soda, and again washing after the last two baths.

On Saturday the 22nd instant I exposed the said six plates. Those treated with the citrate of soda appeared *as good as fresh excited plates.* Those not treated with any bath, after exciting, showed a little decomposition around the edges of the plate; and those treated with the arsenite of soda were too far gone to make a perfect picture to the edges.

It appears to me that there is a small advantage in using a citrate of soda bath, and a decided disadvantage in using the arsenite. I am now speaking from the result of this experiment. A good deal depends, as it would seem from certain circumstances, upon the state of the collodion, possibly, as I have in some of my experiments thought the citrate bath gave a more decided advantage than I have found in my last.

Either in your Journal or in a communication somewhere, you stated that you still thought that the citrate bath after the exciting bath increased the sensitiveness, by enabling you to keep the development up longer without decomposition taking place. I have tried a much weaker developer than I usually make use of, and then I could develop two plates with the same portion of developer without decomposition having taken place to an injurious degree.

The difficulty I experience is in obtaining full definition in dark trees in shadow, without a long exposure, where light objects are also in the picture. To illustrate my theory, or what I really find in practice, I state that where, with sunshine on one side of a street and the other in shadow, I should give a considerably longer time than if the street were wholly in shadow, because in the last case I can continue the development further than in the former.

A stone house without trees — my own for instance — I could get sufficiently exposed in two minutes; but if I take trees in I should give six minutes.

At two minutes' exposure, before I could get the definition out with the tree, sthe house would be as impenetrable to the rays of light as a gutta percha tray.

If you can point out any iodiser which will attack vegetation without over-doing the high lights it would be a great desideratum.

Having heard so much in favour of the Fothergill process I have been induced to invest sixpence in Keens' book. I confess I am not enamoured with the process, having tried it several times, and produced results only similar to specimens obtained by other manipulators which I think inferior to those by Taupenot's process. I do not intend to proceed further with the process at present; but if at our next exhibition Fothergill's process carries the palm, I shall probably go into it in good earnest.

[We have no doubt that the addition of more bromide of some kind to the collodion would enable foliage to be taken with the same exposure as light-coloured objects. The paper by Mr. Heisch, published in our last volume, pp. 135 - 138, proves this very clearly. By using one part of the following iodiser to three parts of plain collodion he was enabled to obtain a *correct* impression in light and shade of *red* and *white* camelias, with *green* leaves and the meshes of a yellowish basket.

IODISER.

Iodide of ammonium	36 grains.
Bromide of ditto	12 "
Chloride of calcium	3½ "
Absolute alcohol	2 oz.

— Ed.]

PRACTICAL HINTS UPON POSITIVE PRINTING.

By Mr. Leake, Jun.

[Read at the Meeting of the South London Photographic Society, October 20, 1859.]

Mr. Leake prefaced his paper by remarking, that as it was intended solely for beginners, the gentlemen present must not expect an elaborate paper upon the theory of positive printing. He merely intended to offer a few hints which he thought might be useful at a time like the present, when most amateurs having returned from their photographic tours loaded with negatives, were anxiously considering how they might produce from them the best positive prints. To assist them in the accomplishment of their purpose, he proffered the results of his own practical experience in the following words: —

I think that to produce good and permanent prints will put all the good qualities of the operator to the test, and consequently the notion that to print a positive is the easiest thing in the world had better be at once scouted, and the idea that it will require all the care of which the operator is master be at once substituted.

I shall first notice the paper — I always use Saxony if procurable, if not I prefer Canson's. I like it of medium thickness; as I find if too thin the prints are deficient in vigour, and if too thick it is, when albumenised, very difficult to tone. As a rule the thick will give the richest print. I suppose nearly all amateurs procure their paper ready albumenised: this is the best and cheapest plan, if a small quantity only be required; the only precaution necessary being to procure it of a good maker, as an inferior paper is dear at any price, leading as it does only to disappointment and disgust.

We next notice the albumenising and salting — Enough albumen should be used to give a fair gloss, but it must be borne in mind that it is not used merely to give a glaze, but to impart a vigour and richness to the prints which cannot be obtained by any other means. I think too much albumen gives an amount of gloss which destroys the artistic effect of the proof, and no doubt retards the toning to a great degree. If, however, it can be toned without sulphuration, the resulting pictures will be of a very rich deep tone. If, on the other hand, too small a quantity be used, the pictures will tone more rapidly, but will be wanting in richness and depth, and will approach in effect prints on plain paper. In selecting a sample of albumenised paper, it will be remembered that it is not always that with the highest polish which contains the most albumen or gives the finest results, as some varieties are glazed by hot-pressing or some other method: this will soon show itself, as in the sensitising and subsequent process it will lose most of its surface. I prefer a paper with enough pure albumen to give a nice even surface without being too highly glazed. Owing to the difference in the sizing, &c., of various papers, the proportions necessary for this result can be determined only by experiment. As regards the salting when albumen is used, a less quantity will be required in solution than will be needed for plain paper, as the albumen will retain more of it on the surface. The quality and tone of the print is materially affected by the proportion of salt, a highly salted paper giving, with a proportionate quantity of silver in the sensitising bath, a richer and more brilliant print than one slightly salted. As I have not prepared any great quantity of albumenised paper myself, I cannot give any positive rules or formula for the process, but must refer the amateur to some of the many works treating of this subject. Albumenised paper cannot be used too fresh. I have no doubt that much of the trouble and

disappointment met with in positive printing is owing to the decomposition of the albumen. I once had a quantity of paper handed over for my use which, when laid on the silver bath for sensitising, left the albumen and salt floating in the solution — a disagreeable peculiarity, which I found attributable to this cause, the same bath giving perfect results with a fresh sample of paper of the same make. I think it a good plan to dry the paper gently at a distance from the fire if it seem at all damp, or if it be damp weather, immediately before placing it on the sensitising bath.

We now notice the sensitising process. — Albumenised paper should always be sensitised by floating. A hundred grains' solution is generally considered to be of sufficient strength, and no doubt is for some qualities of paper, while for others a much stronger bath will be necessary. Of course this will have to be regulated by, and adjusted to, the quantity of salt retained by the albumen; and it is much to be regretted that the manufacturers of albumenised paper do not as a rule specify the amount of salt used in its preparation. As the negatives from which I print are generally portraits, very soft without great intensity, I prefer a bath of from eighty to one hundred grains; this will give a very fine toned proof. At any rate the amount of nitrate should not be allowed to fall below sixty grains, except to print from a very hard negative.

It must be remembered that the colour of the prints is to a great extent affected by this cause — a weak bath giving a cold and faded appearance, while prints from a bath of full strength will, if from a good negative, be of a fine, deep, rich and warm tone.

You need not be afraid of having the silver bath too strong: it will weaken rapidly by use, and take a very large excess to spoil a print, though a slight deficiency will do so most effectually. Some operators recommend the addition of a small quantity of acetic acid to the sensitising bath: I consider this a most doubtful proceeding; in fact (it may be mere prejudice) I do not like acid in any part of the printing process, and always avoid it if possible. If the bath become alkaline by use, which may be known by its removing the albumen, enough acid should be added to neutralise but not acidify it. I generally keep a little kaolin at the bottom of the bottle in which the bath is kept; this keeps it a nice colour, and it *looks* cleaner if it is not. From three to five minutes will generally be found sufficiently long for floating; I think it should not be allowed a much longer time, as the solution penetrates the albumen and is absorbed by the paper, which it rapidly discolours. The paper should not be sensitised long before use if the finest results are desired, as it becomes yellow and the prints look cold when toned. I sensitise my paper the morning I intend to use it; dry gently at some distance from the fire, and place it in a folio between clean blotting paper for use.

The only precaution necessary in the exposure to light is to keep the paper in close contact with the negative. It will be found most negatives print better in the shade than in the direct rays of the sun. I sometimes think a little depth is gained by a short exposure to sunlight by way of finish. This, however, is mere supposition, and I give it for what it is worth.

We now come to the most critical and difficult part of the process, the fixing and toning. To perform this operation properly will require a great deal of care. The primary object most photographers seem to have in view is to produce black tones: black they will have by hook or by crook, and, unfortunately, whether *obtained by sulphur or gold.* The toning bath I would recommend for general use is the old one for fixing and toning in one operation, the formula for which is so well known that I need not repeat it, but will merely remark that very exact proportions are not essential. I have tried most of the new baths, but although some of them give very excellent results I think quite as good may be obtained, *with more certainty* and less trouble, by the old one. Upon removal from the printing frame the proof should be washed in common water till it ceases to flow milky, in order to remove the free nitrate. I consider this important, if *permanence* be desired, for two reasons: in the first place it prevents that sulphureting process which is invariably set up on the addition of nitrate of silver to the hyposulphite bath; and in the second it gives the alarm when the supply of gold begins to fall short, as the prints will then tone with great difficulty and slowness. The utmost care should be taken to prevent acidity of the bath, which may arise from various causes. In hot weather it will often become acid spontaneously, but more often from the chloride of gold containing free hydrochloric acid. To prevent as much as possible inconvenience from this cause, I use two toning baths on alternate days, and immediately after use replace the gold I consider to have been abstracted by the prints toned. By this method forty-eight hours are allowed to elapse between adding the gold and using the bath, thus giving time for the deposition of the sulphur and consequent neutralisation of the bath.* Some operators actually recommend the addition of a small quantity of acid to the toning bath. When this is done the bath assumes a milky appearance, and the prints being immersed in it pass rapidly to a very dark tone, though in all probability they are sulphuretted to a very high degree, and are *not permanent.* To remove any acidity which may arise I use a trace of ammonia, or, if preferred, a little chalk may be kept at the bottom of the bottle in which the bath is kept. The exact quantity of gold used has not I believe been accurately determined, but I do not think more than two prints 10 × 8 can be properly treated by each grain, and if very fine tones be desired a larger quantity may be used. To keep up the fixing power of the bath I keep a few crystals of hyposulphite at the bottom of the bottle. If this be done no further fixing of the proof will be required. It is better not to use a toning bath too long, as it will, notwithstanding every precaution, acquire toning properties, even in the absence of gold, and the accumulation of organic matter will render its use dangerous. I would recommend that the toning process be conducted as soon after exposure as possible, as the paper rapidly discolours; if, however, placed in a dish of clean water they will keep some time without much injury.

In toning albumenised prints it should be remembered that *the natural colour of the photographic image on albumen is pale red,* and that in consequence it will require a more energetic toning bath to produce black tones on *it* than on plain salted paper, and also that a very prolonged immersion in the bath is favourable to sulphuration, yellowness of the whites, and subsequent fading. I think it preferable, therefore, to be content with some of the beautiful tints to be obtained by the process before the black tones are reached, and so insure to a great extent their permanence.

Upon removal from the toning bath the proofs should be well rinsed in cold water; this process should be often repeated, as it is essential to remove the hypo as quickly and thoroughly as possible. To effect this the prints should be placed in a dish of water and turned over several times; the dish then being emptied a fresh quantity of water should be taken, and the same process repeated. They may then be placed in a large vessel, and a stream of water allowed to pass through for some hours, the water being poured entirely off several times. The water should not be turned on and the prints left to take care of themselves, but they should be frequently turned over and separated so as to insure *each picture* a thorough washing. I consider a prolonged soaking quite unnecessary, from twelve to sixteen hours being ample. Some operators recommend washing in hot water by way of finishing the process; but if proper care be taken with the cold, I think this will not be required. When properly washed the proofs may be dried at a moderate distance from the fire, ironed between sheets of blotting paper, and they will be ready for mounting. For this purpose I use a very strong solution of gum, taking care to use it freshly mixed. The prints are much improved by hot-pressing after mounting, and as it is a very cheap process I would recommend it for general adoption.

To recapitulate — I consider that in order to produce the best results by this method of positive printing, the following conditions are necessary: — The paper should be of moderate thickness, and retain a fair proportion of albumen and salt on its surface. The *exciting* bath neutral, and of full strength. The free nitrate should be removed before immersion in the toning bath. The toning bath should be kept neutral, and the supply of gold well maintained. The proofs should be well rinsed immediately on removal from the toning bath; and the operations of sensitising, exposing, and toning, performed if possible, on the same day.

NOTES OF A PHOTOGRAPHIC TOUR IN THE HOLY LAND.

No. VIII.

I RETURNED to Jerusalem four days ago, for it seems impossible to tear one's self away from this hallowed spot, and I linger and linger, even while I know that the longer I stay the less inclined I shall become to depart.

The morning had scarcely broke over the high eastern hills, when a terrible hubbub among my followers startled me from my sleep. No matter how confused one's ideas are in being suddenly aroused from sleep, the instinct of self-preservation is always paramount. I seized a pair of revolvers, and without waiting to dress ran out to seek the cause of the disturbance.

* See Hardwich, page 166 (Fifth Edition), and page 162.

I have, I think, told you how John had got into trouble with some of the Pasha's soldiers, and in his summary way had pitched one of them down a vault. Out of that little episode the present adventure was born.

Three of the resident Pasha's officers with a dozen soldiers had seized on Hassan and his men, on my cook, and in fact on all my retinue they could lay hands upon. Me, you know they could not arrest, for in Turkish countries Franks are protected against it, except by their own consuls or consular agents. It was in vain for the soldier whom John had assaulted to make any complaint against my friend; but he could reach us through our servants, and the lying knave had complained of them as accessories to the assault. Hence the present hubbub. I have no doubt in my own mind that the guard had told the truth, but this arrest was an invention of an officer of the Pasha's, whose skill at extracting *backsheesh* out of travellers is well known. The plot had been hatched out during our absence. I was not precisely in the dress to appear dignified as I emerged from the tent among my captive followers; but clothing is a small matter in the East, and to an Oriental, accustomed to the various dresses of Arabs, sheiks, dervishes, and holy men, I suppose I presented as impressive an appearance in fluttering linen as I should have done in coat and trowsers.

I heard John's stentorian voice,

"Who are you? and what are you about?"

When you have heard seven Arab voices running over all the keys of the East—and there are several more octaves than you ever dreamed of—you will have some approximation of the confusion of tongues at Babel.

An insolent reply from the officer was all John got to his question, and I can scarcely venture to guess what would have followed but for my appearance with the revolvers. A significant pause ensued, for a pious horror of Frankish weapons possesses the Arab soul; and of late years the idea has gained ground that a Frank does not much care who, what, or why he shoots—from which idea, carefully maintained by those whose duty it is to maintain it, much good to the traveller may result.

"God is great! If the Effendi will listen ———"

"I will listen to nothing! Let go your hold of Mustapha Achmed Barikat! How dare you touch my cook—son of a starved hound!—when the breakfast is but half ready? Do you not know the penalty of interrupting an Englishman at his breakfast?"

A contiuous thunder of abuse brought the unlucky officer to his senses and his hand to his forehead, while he politely begged permission to execute his orders, which were to bring our attendants before the Pasha, who held court on the site of Pilate's house, within St. Stephen's gate. We yielded them all except our cook and one man, who served breakfast as rapidly as possible, and then followed us to the court of this high and mighty Pasha, of more or less tails, I dont yet know how many.

As we were entering the gate of the city we met our American friends coming out. They turned round with us, so that we made a respectable cavalcade with our horses, mules, and donkeys, as we entered the door-way of the House of Judgment.

His excellency was comforting himself with a *shee shee* (or water pipe) and the converse of a friend. As our party entered I did not at first recognise his companion, but the next moment I was in the arms of Mohammed Bey, who, I supposed, had returned to Damascus more than a week ago.

He presented me to the Pasha with infinite respect, and our business was despatched in an instant. The wily officer who had planned the attack was frightened out of his senses, and, by the way, he put down his feet as he walked. I could see that the leathern thong was in his soul: in fact, this high and distinguished governor begged to be permitted to evince his affection for his friend and the friend of Mohammed Bey by whipping somebody then and there. Of course we politely declined the favour. But the Pasha was not easily satisfied. He proffered various services; and if he could have identified the soldier who had dared to call a respectable traveller "Christian dog!" I verily believe he would have laid violent hands upon him, and buried him alive in the pit into which friend John threw him.

Business ended, we talked awhile, and then ascended to the top of the house, and looked at the sacred enclosure from that commanding position. We remained up there half-an-hour. I reserve a description of it for another letter, since I have an engagement with Sheik Mohammed, the principal sheik of the mosque, to visit the interior some day, and thoroughly explore it.

When we came out of the Pasha's house we paused a little while just inside St. Stephen's Gate, to look down into that vast pit or pool, which is commonly called the Pool of Bethseda. I will not venture an opinion on what it really is. It is by some supposed to be the remains of the trench which guarded the north wall of the tower of Antonia, and the temple area. It is still the northern boundary of that space, and is overhung on the south by the high walls enclosing the Harem or sacred place. Two arched vaults open in it, leading up under the Governor's residence; but these are quite choked up with stones and rubbish. It is at best, then, one of the mysterious relics of ancient Jerusalem, which we look upon with profound and melancholy interest. Around it stand tottering walls, and all the signs of desolation that sadden the Holy City. Minarets are standing pointing heavenward here and there near the lonely pool; but no angel descends to move the waters—no sick man finds healing in the flood—no Saviour approaches to bid the weak and weary sons of men rise up and walk.

A mysterious sadness grows upon me as I linger about Jerusalem. All is so mournful, so inexpressibly solemn. The very sunshine on these crumbling walls is unlike sunlight elsewhere and has no cheer, no gladness in its beams. I lingered all the morning within the gate—clambered into the dry basin of the pool—gathered some flowers from its sides—and listened like an old man while John and his friends talked, as it seemed to me, like children. And then we walked together down the hill into the valley; passed the tomb of the Virgin Mary, and the wall of the Garden of the Passion, till we came to the monolith, known as Absalom's Pillar. Here we sat down on the pile of stones that has accumulated around the monument—for every passer-by hurls a stone at the monument of the disobedient son—and the sun travelled westward. When shall the succession of morning, noon, and starlight over down-trodden Jerusalem have an end? When will God call Zion from desolation, and give to Salem the blessing of peace?

Are you not tired of my notes from this sad city? There is nothing to write about but ruin and its story, decay and its memorials. And yet I feel at times a pride—a tenderness mingled with a majestic pride—as I look down from the side of Olivet on the City of the Great King, for I know that the Lord will build Jerusalem, and I thank Him that my eyes have seen her even in her desolation. We may not live to see it, but the elders that carry the saint's prayers bear many vials full of those that beg the restoration of the sceptre of Judah; and the day cometh—the day will come!

D. T.

Meetings of Societies.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

The ordinary monthly meeting of this Association was held at Myddleton Hall on the evening of Wednesday, the 26th ultimo, George Shadbolt, Esq., Vice-President, in the chair.

After the usual business of the meeting, reading and confirming the minutes, &c., had been disposed of, the Chairman handed round, for the inspection of the members, one of Messrs. Smith, Beck, and Beck's very beautiful mirror stereoscopes, and gave an elaborate description of the same. [An article on the Mirror Stereoscope is in type, and will appear in our next number].

In the absence of Dr. Ryley, who had promised to give the result of some further experiments on a modification of the collodio-albumen process, the meeting assumed a conversational character, and Mr. Hill informed the members that in a recent conversation with Mr. Fothergill on the process named after him, he, Mr. F., did not now limit the washing of the plate on its removal from the nitrate bath to a limited quantity of water only, but washed them in running water until all greasiness had disappeared.

Mr. M. S. Legg presented four well-executed proofs—pictures from negatives by the meta-gelatine process—for the folio of the Association, for which the thanks of the meeting were accorded to him.

Mr. D. W. Hill and Mr. Shave exhibited stereoscopic pictures from "Fothergill plates," and the Rev. J. Winter negatives on Taupenot's and Dr. Hill Norris's plates.

Mr. D. W. Hill also laid on the table two large pictures from Fothergill negatives—the first washing having been performed in a two-grain nitrate wash. Mr. Hill always pours on the albumen at the lower end of the plate after draining.

Mr. Gamham exhibited several pictures from Dr. H. Norris's plates.

Mr. Hare exhibited a portable elongating camera, adapted either for portraits or views. It was, when set up, perhaps the most rigid portable camera yet introduced. The body was made of velveteen.

The thanks of the meeting were voted to Mr. Hare.

The CHAIRMAN called the attention of the members to a dozen stereoscopic pictures of very high character, taken by Mr. Archibald Burns, of Edinburgh, with the Fothergill process. A very remarkable effect was produced in one of *Roslin Chapel* by the reflection of light ON the glass of the windows in front, and *through* the glass of windows in another part of the building. They were pronounced to be highly satisfactory by the most exacting of critics. [For description of these see page 267].

Dr. RYLEY having arrived, he recapitulated the particulars of his experiments described at page 137, vol. vi. of *The Photographic Journal*, and page 181, vol. ii. of *The Liverpool and Manchester Photographic Journal*. The further alleged discovery he had now made was, that by pouring a solution of gallic acid on the plate after washing the sensitiveness of the plate was restored, its keeping qualities insured, and solarisation prevented.

Mr. D. W. HILL reminded Dr. Ryley that there was no novelty in his discovery: it was identical with that described by Major Russell.

Mr. HISLOP said the only difference in the process was in using cold water instead of hot.

After a little wandering from the subject, Dr. RYLEY asserted it was simply impossible to take a picture by the Fothergill process as described by the originator in his letter to *The Times*.

Mr. SHAVE and also Mr. BINGHAM called Dr. Ryley's attention to the *fact of their having exhibited negatives by that process, and prints from them*, at the meeting of the Association held within a few days of the publication of Mr. Fothergill s letter.

A vote of thanks was given to Dr. Ryley; and on a further discussion ensuing, Mr. LEGG asked Dr. Ryley (who contended that the sensibility was owing to the alteration of the structural condition of the film consequent upon coagulation of the albumen) if he had examined the film under the microscope, and whether the result of his examination led him to the solution of the question, "whether the alteration was chemical or mechanical?"

Dr. RYLEY was not prepared to answer that question.

Mr. HANNAFORD thought that collodion sensitised with a simple iodide was not so sensitive after washing as if a bromide or other salt were added to the sensitiser, and that, with iodide and *some other* silver salt, free nitrate was not necessary to render the plate sensitive.

The CHAIRMAN agreed that this was an opinion worthy of attention, as it was well known that in presence of free iodine any other salt of silver would be converted into an iodide; and it was not improbable that the presence of iodide of silver in a nascent state might be the key to the sensitive condition.

Mr. WHARTON SIMPSON promised to read a paper at the next meeting *On the Positive Collodion Process, with some remarks on the Alabastrine Process.*

The meeting then adjournod until the 30th instant.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE first meeting after the vacation was held at the Lecture Hall, Carter Street, Walworth, on the evening of Thursday, the 20th ultimo.

The Rev. F. F. STATHAM in the Chair.

The CHAIRMAN called attention to the proceedings of the evening, prefacing his notice with some few remarks relative to his election as President, an office he had been induced to accept, not because he had any *practical* knowledge of photography, but solely from his ardent love of science, and especial admiration for the photographic art. He trusted that he should perform the duties of his office to the satisfaction of the members.

Mr. A. H. WALL, Honorary-Secretary to the Society, next addressed the meeting as follows:—

Mr. Chairman and gentlemen, this being in point of fact the first meeting of the "South London Photographic Society," devoted to its real business, I may perhaps be permitted to call attention to some few matters relative to its future purposes and existence.

The ultimate amount of utility and success which such a society as we represent may command, appears to me to be dependent upon the proper combination of certain elements, viz., photographic chemistry, photographic optics, photographic manipulation, mechanics as applied to photographic apparatus; and, although last not least, that knowledge of the leading principles of art, without which the learned chemist and talented optician, with all the manipulatory skill of a clever photographer, provided with the best apparatus, cannot produce effective or pleasing results.

Our President, the Rev. F. F. Statham, is a gentleman well-known for his chemical acquirements and scientific attainments generally, and I dare say, gentlemen, it is known to most of you that already one of the celebrities of the photographic world, Mr. Sutton, has announced publicly his obligations to this gentleman for his earliest knowledge of chemistry. Our Vice-President, Mr. W. Ackland, as a photographic experimentalist and the author of several works upon different branches of photographic art, is, of course, known to most of you. Mr. Shadbolt, I am proud to say, also one of our members, * * * * My friend, Mr. Noldwritt, a scholar of varied accomplishments, has watched the rise and progress of photography with no small interest and study, and beyond doubt is in possession of much information of an interesting and instructive nature. The name of Mr. Hannaford is familiar to you as one of our most talented amateur photographers.

Not to be tedious, I will briefly add that in Messrs. Leake, Sen., Leake, Jun., Cotton, Hook, Howard, Clarke, Hervé, Chapell, and others, we have practical or professional *photographers* of no mean ability; that in Messrs. Hervé, Keens, Rogers, Hannaford, and others, we have *artists* of professional repute or amateur skill; that in Messrs. Clarke, Leake, Sen., and Leake, Jun., we have, I believe, capital *mechanists*, and that in our Secretary we have a very "willing horse," but I fear one not sufficiently competent in the branches of knowledge more strictly and practically photographic. But now, gentlemen, having told you what we have, and congratulated you with good reason upon its possession, I want to conclude with a few words upon what we have not.

First, although we have perhaps as many or more members than we could reasonably expect, we have not enough. Members represent money; and although money is a very vulgar thing to allude to, it is no less the "sinews" of art and science than "of war." How to increase our members is therefore a question of primary importance. There is one way of doing this which I wish to point out (of course many other means of pursuing the same desirable object are in existence), and that is by the formation of a circulating collection of stereoscopic and photographic pictures for the benefit of members. This we may very speedily obtain if such of our members as possess stereoscopic and other negatives will generously present their society with copies of the same, and appeal to their photographic friends, *in the name of a society devoted to the advancement of photographic art and science, which, in common with every similar institution, has a just claim upon their kindly sympathy and support*, for contributions also. By so doing we offer attractions to those who, without being practical photographers themselves, would be glad to secure such an advantage, and by thus increasing the Society's funds, enable your Committee to organise and bring about fresh advantages for present members, and consequently further inducements for future members. I need not state that, as Secretary, I shall very gratefully acknowledge any such contributions that may be sent to me at 90, Cannon Street, West, City; I shall be also very glad to receive papers upon phographic subjects, to be read at our meetings, as also any correspondence relative to the exhibition of apparatus, &c., or names and addresses of such as may be desirous of being nominated and elected for membership.

The PRESIDENT having seconded Mr. Wall's appeal for the folio, and called attention to other objects connected with the Society,

Mr. H. L. KEENS, Sen., was then called upon to read his paper, entitled *Truth in Art Illustrated by Photography.* [See page 268.]

At the conclusion of Mr. Keens' paper, which was received with expressions of applause,

The PRESIDENT remarked that, beyond a doubt, the cause of art had been efficiently served by the introduction of photography, and that the spirit of improvement traceable in the productions of modern art was justly due to its influence, although the fact was not perhaps fully acknowledged just now. There were too many artists who still held the pernicious doctrine, that it was their high mission, not to copy, but *improve* upon nature, who had done more to lower and degrade their calling than could be briefly calculated. But that such was not the opinion of the great masters could be easily proved; for instance, among Raphael's celebrated drawings at Oxford, which when there he frequently and carefully studied, was a picture of the *Magi*, into which an elephant had been introduced, and he found that before Raphael painted that animal he made at least twenty careful drawings of it in various positions—not mere sketches, but finished productions, full of laboriously executed details, even the peculiar bosses and wrinkles of the skin and creases upon the trunk being scrupulously copied. If photography re-created this spirit of industry and patient care, and called modern art back to this *Raphaelism*, it would, he inferred, speedily extinguish the school called *pre-Raphaelite.*

Mr. Wall thought the picture of the *Charitable Girl and the Beggar* not only defined Mr. Keens' idea of "truth in art," but also its advantages. In a painting of this incident, without doubt, "the whole truth, and nothing but the truth," would best serve the highest aim of morality and religion, and consequently secure to the artist the highest and most valuable reward of art. There was nothing in the beggar to awaken interest in the breast of a romantic girl:—he was dirty and repulsive, and therefore it was the pure holy and christian feeling of charity alone which moved the young girl's melting heart and prompted her outstretched hand. Mr. Wall also agreed with the author of the paper in thinking that perfection of detail could in no way detract from the high purpose of such a picture; for, however truthful, and consequently beautiful, the imitation of silk or satin drapery might be, he should not envy the mind or heart of a spectator who found such things more attractive than that sweet expression emanating from the angel of compassion—an expression which was more frequently than any other seen upon the divine face of the great Saviour of mankind.

In such a scene an artist would find every quality he required—contrast, sentiment, loftiness of purpose, &c.—and the photographer nothing beyond the capabilities of his camera, if it were only possible, by the pistol or some other such arrangement, to obtain a picture without the cognisance of the principal actors. He would only add a few words to say, that while we decry bad painters, it should be remembered that we *sometimes* see bad photographs, as far below that of bad pictures. The speaker then concluded with some few remarks relative to the advantages photographers possessed in the existence of societies for the advancement of their art.

Mr. Keens said, the chairman's remarks reminded him of some observations made to himself by an Italian artist, painting at Hampton Court, who pointed out to him the extreme accuracy of detail presented by the cartoons, even in the representation of the fingers, the muscles of which were in their action almost as eloquent of the varied feelings as those of the faces—the upraised hand of the preacher, in *St. Paul Preaching*, contrasting finely with the almost paralysed appearance indicated by the drawing of the muscles in the hands, arms, &c., of the intently listening figures around.

Mr. Leake, Jun., then read a paper, entitled *Practical Hints upon Positive Printing*. [See Page 269.]

At the conclusion of the reading of the paper several beautiful specimens of photographic portraiture were handed round, as Mr. Leake's productions by the process he had described.

Thanks having been voted to Mr. Leake for his able and eminently practical paper,

The Chairman hoped to hear some remarks from the practical photographers before him. He would take that opportunity of impressing upon the gentlemen present the importance of carefully observing any thing unusual or accidental which might occur in their photographic practice. It was his belief that no science or art was so much indebted to accident for its discoveries and improvements as photography was. If every gentleman in whose experience a fact transpired for which he could not account would make a note of the same and bring it forward at these meetings, he had no doubt but they would form a most interesting collection, and lead by discussion to very valuable experiments and results.

Mr. Hannaford thought the subject of positive printing was a matter of vital importance, and that hints upon such a subject deserved their best thanks. In looking over our prints we all found a greater or smaller per centage of them faded; but whether or not photographs toned by the alkaline *gold* process would prove more uniformly permanent than those by the old process advocated by Mr. Leake must be left for time to decide; but are we sure that the old toning came from gold and not from sulphur? and as the prints remained but a short time in the fixing solution, it appeared to him that the advantages were decidedly in favour of the alkaline toning bath. He had tried Maxwell Lyte's process with the phosphate of soda with great success. Recently he had employed acetate of soda with gold. The advantage gained by it was, that over-exposed prints could be toned down very considerably, and on the addition of a small quantity of carbonate of soda the prints would continue to darken with but little further deduction.

He had made a great number of experiments in printing with the salts of various metals—iron, copper, cobalt, &c.—and exhibited a few specimens in iron. His only difficulty was in procuring pure whites; he was at present of opinion that none of these new processes stood any chance of superseding the use of silver, but they formed subjects for very interesting experiments, which probably might lead to some useful results. He hoped at a future time to read a paper upon this.

Mr. Howard stated that he must certainly agree with Mr. Hannaford in regard to the alkaline chloride of gold bath, as he had met with a deal of trouble by using the toning bath advocated by Mr. Leake, in the discolouration of his prints, which fact induced him to cease using it, since doing which he had never had any symptoms of fading, the whites being always good and pure. In the hands of professional printers no doubt good results were obtained by Mr. Leake's process; but he thought amateurs would derive greater satisfaction from the use of the other bath. He regretted that he was not chemist enough to advance any stronger arguments.

Mr. Hughes thought the old toning bath was theoretically defective. We never knew in using it whether the tone of our prints was really due to sulphur or gold; but in using the alkaline bath we were at least sure that sulphur had nothing to do with the toning. By its use also we could obtain any tone we pleased—chestnut-browns, purple-browns, purple-blacks, violet-blacks, and if there were any who desired such, cold inky-blacks. With regard to its economy, he knew by experiment that with one grain of gold he could tone five hundred square inches of albumenised paper, as he had proved by careful and repeated experiments.

Some prints were now examined, the peculiar mottled and yellow patchy appearance of which was attributed by Mr. Hughes to the use of a too weak solution of hyposulphite (or possibly from their not being exposed long enough to its influence).

The Chairman announced a paper on *The Difficulties of the Dry Process*, by Mr. W. Ackland, for the next meeting, on Thursday the 17th instant.

Mr. Hannaford promised a short paper, to be called *Photographic Jottings*, for the same evening.

The Secretary hoped he should be enabled to bring forward a fine collection of photographs for inspection on that occasion, and after a few concluding remarks relative to the advisability of reopening the discussion which had just ceased, called upon the meeting to proceed to the election of new members.

The following gentlemen were proposed and elected:—Messrs. Stevens, Armstrong, Luckin, Hughes, Hook, Ottley, Stevens, Wood, Chapel, and Keens. The business terminated with a cordial vote of thanks to the chairman.

LIVERPOOL PHOTOGRAPHIC CLUB.

The twelfth meeting was held at Mr. Keith's Rooms, on Tuesday, the 18th ultimo.

Mr. Glover exhibited an extremely curious print, representing the same face under eight different phases, commencing from a profile on the left side, and gradually turning until the full front, and ultimately the profile on the right side, became visible—the whole arranged in an uniform plane radiating from one common centre, so that if mounted on a card with a small hole above each print, in imitation of a toy with which many are familiar, would represent the head as continually turning. This was contributed by Mr. J. Dean, of Douglas, and excited much controversy as to the mode of its contrivance.

Mr. Keith laid before the meeting a very pleasing print of the whole of the military pensioners employed here as commissionaires. They were most artistically arranged, clustered in a pyramidal form round a nine pound gun, the topmost figure supporting the Queen's colours. The group had a most striking effect. It had been taken by desire of Colonel Falconer, for the purpose of being laid before Her Majesty; but Mr. Keith's philanthropic object was to make their cause better known, with a view to their being more generally employed, as their appearance had only been regarded with curiosity up to the present. He intended distributing copies to the press and public offices.

Mr. Bell called attention to a print he held in his hand, received from Mr. Shaw Smith, of Dublin, as the standard of excellence he required in those prints that were to be sent to him as exchanges—the prints that Mr. Bell had hitherto sent to him, though executed by some of our most proficient photographers, and regarded with very high favour by the members, and well known to fame by the world at large, not being deemed to possess adequate merit. The specimen was a view of the exhumed wonders of Petra; but, excepting the subject, it was inferior, red in tone, and not happily selected in an artistic point of view.

Mr. Bell also exhibited some of the new salt iodo-cyanide of potassium, concerning which a paper had been read by Dr. J. Milton Sanders before the American Photographical Society. The marvellous rapidity with which it removed stains and discolouration of silver excited great admiration.

CHORLTON PHOTOGRAPHIC ASSOCIATION.

THE monthly meeting of the members of this Association was held on Wednesday evening, the 12th ultimo, Mr. NICHOLSON, the Vice-President, in the chair.

The minutes of the last meeting having been read and confirmed, it was proposed by Mr. ROGERSON, and seconded by Mr. HOOPER, that Mr. Griffiths be admitted a member of the society. Carried.

Mr. HOOPER stated that he wished to postpone the paper he had promised for that evening, *On the Production of Large Waxed-Paper Negatives*, as he hoped against another meeting to be able to lay before them the results of some experiments he had been making with a paper prepared with albumen. He had not yet been able to try this paper in the camera, but judging of it from an exposure in the printing frame, he believed it would be found to be more sensitive than waxed-paper, and as the picture would be kept more on the surface, a clearer definition would be gained. Mr. Hooper then proceeded to develop several prints produced on each kind of paper:—those on albumen had only been exposed two minutes, and those on waxed-paper five minutes; the former appeared the more successful of the two.

Mr. RADCLIFFE exhibited an albumen frother, to be worked with a drill bow. The instrument appeared simple and effective.

A discussion on some minor subject followed, and a vote of thanks to the chairman concluded the business of the meeting.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

AT the last meeting of this Society, Mr. J. T. BROWN read a paper *On the Application of Photography to Art and Art Purposes, and more especially to Painting*. It was altogether of an introductory character, being mainly devoted to a history of painting, the periods when it flourished and declined, and the causes of decline. Seeing that art is so greatly dependent on the various chemical changes produced by colours, he considered all ought to aid in tracing the effects resulting from the different degrees of refrangibility of rays producing the solar spectrum, and by a careful analysis of their actinic action upon the many photographic agents within our reach, establish a series of data by which the artist should be enabled to distinguish the colour of the ray by which the change was produced. Photographers might then lay their craft more fully before the artist, who would more willingly avail himself of the power of arresting the pleasing variety of form with which he may meet amongst those ever-changing glories of the sea, the clouds, the fields, the lower animals, and man—and lay up a store of knowledge obtained at a moment when without such assistance it might be lost to him for ever.

By these means not only would photography be extended, but the art of painting would be benefited. The photographic image need not be servilely copied, but artists might adopt the course taken by Claude. "The country was his study, and the objects around him; and the effects produced by the varied illumination of morning, noon, and evening, were as guides which he obeyed or controlled as best suited his purpose—not imitating servilely what he saw, but employing it as the regulator of his taste."

Mr. Brown, in conclusion, dwelt on the connexion of pure colour with profound noble thought, quoting Ruskin's fine passage:—"If the blue were taken from the sky, the gold from the sunshine, the verdure from the leaves, the crimson from the blood (which is the life of man), the flush from the cheek, the darkness from the eye, and the radiance from the hair—if you could see for an instant white human creatures moving in a white world, you would soon feel what you owe to colour. The fact is, that of all God's gifts to the sight of man, colour is the holiest, the most divine, the most solemn."

No discussion followed the reading of this paper.

The third annual meeting of the Society was held on Tuesday evening last, at the Odd-Fellow's Hall. The chair was occupied by Mr. T. MORRIS, and there was a good attendance.

The Honorary Secretary, Mr. C. L. HAINES, read the following—

ANNUAL REPORT.

During the past year of your Society, which your annual meeting brings to a close, you have had several highly interesting and instructive papers read at your several meetings, and your Council can only regret that the poor attendance at several of them could hardly justify the trouble taken by the various gentlemen who kindly prepared them. Your Council therefore deem it their duty to again urge upon you the necessity, for the welfare of your Society, of a better and more regular monthly meeting. During the past session you have not only been favoured by papers from your own members, but also by many lengthy remarks by other gentlemen who have kindly undertaken the task for your edification and instruction; amongst others may be mentioned, Mr. Johnson and Mr. Woodward, the latter of whom is well known as the inventor of the solar camera, and who both exhibited his apparatus and also many beautiful prints taken thereby. It was intended by your Society to hold an exhibition at Aston Hall, in March last, but subsequently, on account of the apparent uncertainty as to the time of such exhibition, it was resolved to postpone it, at all events for the present year. Your library has been increased by the addition, during the past year, of several books, and your Council would remind the members that any book may be obtained on application to the secretary. Your album has not as yet had so many contributions to its pages as your Council could wish, and they would therefore again request the co-operation of all in contributing at least their mite towards this part of the Society's work. The funds in the hands of the treasurer are £7, 18s. 9d., which, together with £5, 15s. 6d., owing from members to the Society, makes a balance in favour of the Society of £13, 14s. 2d.

The only business remaining to be transacted was the election of officers for the ensuing year, and these were appointed as follows:—

President, Wm. Bagnall, Esq.; *Vice-Presidents*, Messrs. W. B. Osborn and C. L. Haines; *Treasurer*, Mr. J. T. Brown, Jun.; *Secretary*, Mr. E. W. Ball; *Council*, Messrs. T. Morris, Brittain, Dr. Hill Norris, W. Hart, A. Edwards, T. D. Clare, W. R. Holyoake, and Hunt.

On the motion of Mr. OSBORN, it was agreed to abolish the half-guinea entrance fee.

Practical Instructions on Coloring Photographs.

By ALFRED H. WALL.

CHAPTER V. *(continued)*.

COLOURING ON PAPER WITH DRY COLOURS.

I have never seen a pleasing effect produced upon paper by the use of dry colours, and it seems to me that these colours are as unfit for paper as oil colours are for collodion, in either case, however, both are used.

The albumenised paper is best, and before applying the colour it should be rubbed with very fine pumice-stone powder. The process of colouring has been already described.

ON THE TREATMENT OF IMPERFECTIONS.

There are certain defects to which the pictures of the best of operators are liable, in the shape of black and white spots and other markings. Various mixtures of water colours, opaque or transparent as may be necessary, are used to conceal these. For white spots, Indian ink with or without a little madder brown or sepia is best; for dark, white with a little Naples yellow, Indian ink, Venetian red, burnt sienna, &c. may be used, mixing two, three, or more colours to a tint which approximates most nearly to the tone of the photograph or colours of the part about the spot. If these spots are on the collodion they are best touched out *after varnishing*, inasmuch as this would so affect the water colours that however invisible the touches were when dry and dead on the collodion they would start prominently into sight under the varnishing, and defy all future attempts to conceal them. When the spots occur upon the flesh try the effect of your mixed tint upon the corner of the picture before applying it, remembering, if it be a black one, that the thickness of colour must give a surface just as opaque as that of the collodion.

It does sometimes occur that, owing to the greasiness of its surface, the lighted parts of the hair will be unpleasantly white, or in the eyes of some horror-struck sitter, GREY: a coat of Indian ink carefully applied with a somewhat dry brush and a very little gum-water will remedy this. Indian ink may also be used to strengthen the outline round the iris, when, owing to the milky blue of the sitter's eye, it is nearly or quite invisible, or from other causes lacks definition and sharpness.

UPON COLOURING HIGHLY.

The pictures best adapted for a process of colouring which resembles pastel paintings are large heads, and no colours are so well adapted for colouring highly as Messrs. Reeves's new "absorbent colours," working with perfect smoothness and evenness you will find them as pleasant to use as they are effective when used. It should be remembered, more especially with regard to highly finished work, that the best of dry colours are so slightly tenacious that the surface upon which they are applied cannot be too quickly secured under glass; with ordinary care, however, the colouring of

these pictures is tolerably permanent. Moisture will injure them, and they must not be exposed to strong sunlight, and of course much must depend upon the choice and preparation of your pigments in this as in every other branch of colouring.

With a few rules for the students guidance in finishing highly, I shall quit this branch of my instructions for the next, viz., water-colours.

To obtain brilliancy, increase the body of colour by repeated applications. See maxim 17.

For the retiring portions of your flesh, and to most of the finishing tints, add grey. See maxims 37, 41, 70.

In highly finished pictures colour the shadows, even the deepest, but only before varnishing. See maxims 42 and 43.

Keep the background near the head lower than the half tints, and lighter than the deeper shadows. See maxim 53.

Let your last touches be given with a *very light hand*, and let them be more definite and forcible in effect than their predecessors.

Select for this process such pictures as have strong shadows and well-defined half tints—an over-exposed picture being perfectly useless, inasmuch as the body of colour would soon bury the outlines beyond the chance of recovery.

Carefully preserve the purity of your tints in the highly lighted passages.

To finish highly requires no mean skill, great experience, and good artistic knowledge; and when all your difficulties are mastered in this branch, the effect obtained will never be so satisfactory as that to be secured in one-half the time by the use of either oil or water-colours.

The author of the preceding paper has, in order to render his communications of greater practical value, kindly undertaken to criticise the work of, and give advice to, students in colouring, through the medium of these pages, for which purpose specimens may be sent, with a stamped and directed envelope *for their return, to* A. H. Wall, Esq., 11, The Terrace, Walworth.

A. S.—If you find the new colours adhere more easily to the alabastrine varnish than the preparatory solution, there is no reason on earth why you should not use it.

Annie.—The picture sent is coloured very carefully and cleanly; a little more brilliancy in the high lights is all that could be desired. I should not hesitate to offer you employment at my own establishment if we needed assistance in that branch. See an advertisement on page four of the last number, or make personal applications to *respectable* parties.

J. B.—Purchase the preceding numbers. I can assure you they contain no information that is not of absolute importance. Your picture is a photographic gem — quite an artistic production; but I cannot say much for the coloured one. Try water colours. I do *not* think you will ever improve a paper print with dry colours.

James.—Certainly not *very* promising, but, perhaps, not *much* worse than could be expected. Yes; I promise faithfully to inform you when I think your case is hopeless (why should I not?); but for the present *persevere*.

PHOTOGRAPHIC SOCIETY OF SCOTLAND.

Regulations of the Fourth Annal Exhibition.

The Fourth Annual Exhibition of the Society will be opened on the 16th December, 1859, and will be closed in February, 1860. All descriptions of photographs will be admissible. It is strongly recommended that each picture should be framed and glazed, with a margin of mounting board, not exceeding two and half inches in width all round. It is also recommended that in the case of pictures smaller than nine by seven inches, four should be in one frame; but a frame containing more than one picture must not exceed twelve square feet in area.

Each picture must have written distinctly on the back the name of the subject, the artist, and owner; the process (calotype, waxed-paper, turpentine-waxed-paper, albumen, the different varieties of of the collodion process, &c.), and if for sale, the price. Exhibitors are requested to be careful in specifying the particular process by which their pictures are taken, in order that it may be inserted in the catalogue.

Pictures touched by the brush will not be admissible unless so described.

A commission of 10 per cent will be charged on all sales made during the exhibition.

Two *Silver Medals* will be given for the best two pictures in the exhibition. One of them to be given for the best portrait or group, and the other for the best photograph of any other subject.

The *Maconochie Welwood Prize* of £10, to be competed for by professional members of the Society only, will be awarded for the best photograph, other than a single portrait. The same picture cannot be put in competition for the Maconochie Welwood Prize and for the Society's Silver Medal; and pictures in competition for any of the prizes must be untouched by the brush, and must be exhibited by the artist himself.

Works intended for exhibition must be delivered, carriage paid, at the Rooms, 90, George Street, Edinburgh, on 1st December next, after which none can be received. A list of the photographs sent must be enclosed in the case, and a duplicate list forwarded by post to the Honorary Secretary. At the close of the exhibition, the pictures will be carefully packed and returned, carriage paid, to the owners. C. G. H. KINNEAR,

49, *Northumberland Street*, Hon.-Sec.
Edinburgh, *Oct.* 1859.

Letters to a Young Photographer.

No. XXII.

My dear Eusebius,

The skilled artist is shown in his full appreciation of the relative value of *tones;* the unskilled painter fails because he attaches too much value to *hues*, and too little to tones. One of the most important things photography teaches us in the principles of art is this value of tones. I have already explained to you the meaning of this term, but it will not be amiss to repeat it, and to show why it is to be preferred to the terms usually substituted for it—*tints* and *shades*. Tone is equivalent to intensity, and is comparative. If you take Prussian blue and add white to it in increasing quantities, you will produce various *light tones* of blue; and in like manner, if you add black to the pure pigment, you obtain various *deep tones* of blue. These are usually called, respectively, *tints* and *shades;* but as these terms are often used to designate a change in colour or *hue*, it ensures more precision and less liability to error to employ the word *tones*. Moreover, there is an analogy in the use of the word in music: we say a loud tone or a low tone to express difference of intensity, the note remaining the same, neither graver nor sharper. The addition of black and of white to a pure pigment does not alter its *hue*, as the addition of another colour does, but only its intensity or *tone*.

Colour, in objects, possesses a value as tone which is independent of its tint as colour. This has to be taken into consideration by the engraver, who has to translate colour into tone; and when the subject is a picture by Turner or Diaz, you may imagine the extent of his difficulty.

Strange anomaly! Artists speak of *colour* where we can discover none; and where we see any quantity of bright colours they say—"this picture lacks colour." An engraving, or a drawing in monochrome, as sepia, bistre, or Indian ink, the artist will tell you is rich in colour! You look in vain for blues, reds, and greens. What he really means is that the subject is well executed in showing due regard to the relative value of tones. Thus, in *colour*, besides light and tint, there is another element—*tone*, or intensity. The painter imitates these three things at one and the same time; the photographer has to be content with light and tone, yet his works are rich in colour, in one accepted sense of that word.

But many colours, and still no colour! That sounds like a paradox, yet artists the most skilled in their art will so express themselves when the productions of a painter with no genius as a colourist are presented to them for criticism. The picture may be as lavishly enriched with the brightest yellows, blues, greens, purples, and reds, as any Turner ever painted, yet it lacks colour! It lacks the proper recognition on the part of the painter of the relative value of tones. Bright and gaudy it may be, but all the delicate appreciation of the power of *chiaroscuro* may be wanting, therefore it lacks colour, or rather, strictly speaking, tone.

Do not forget, my dear Eusebius, that whenever colour is spoken of in an artistic sense, it consists of three elements—of light, of tint, and of tone; and that a painter will consider himself a colourist even while his pictures are deficient in one or even two of these elements.

Now, in a good photograph you are always sure of two of these three elements—light and tone, and you have then what artists call colour, when speaking of works in monochrome. You have perfect *chiaroscuro*, far more elaborate than the most skilful artist's hand can accomplish. Possessing these grand essentials to pictorial representation, why sigh for local colour?

Science often proves and establishes as a law what may have been practised from experience for centuries previously to the discovery of this law. In M. Chevreul's work, on the *Contrast of Colours*, he says, that theoretically speaking, a correct pictorial representation of an object may be produced by black, white, and the local colour. The practice of some of the greatest painters has been in comformity with this principle. Their pictures were highly finished in *chiaroscuro*, like an engraving, although not always strictly in black and white, but in some transparent brown for the shadows and white for the high lights — the intermediate tones of grey by suitable mixture of the brown with the white. I remember seeing a picture in the British Institution, some years ago, painted by one of the great Dutch masters. It was painted in *chiaroscuro*, in burnt umber and white, and it excited my greatest curiosity and admiration. All that was wanting to complete it as a picture was to apply transparent local colours in their appropriate places.

After all, the photograph is deficient in one important element. It has not the artist's power of transforming: it is terribly literal. It takes things as it finds them, and possesses no power to arrange, select, or combine. Therefore you will have to teach yourself many things in your vocation of art-photographer which to the painter are of very secondary consideration.

To produce all the best effects of *chiaroscuro*, upon which the excellence of your works depends, you must be very particular in selecting the best point of view, and the most favourable hour of the day, when the shadows fall nearly horizontal. How can you do this before you have made yourself acquainted with the principles of art? What do you at present know of the laws of relief, of invention, of composition? and who will take the trouble to teach you, if I don't?

Your camera is a machine, and you are a mechanic, unless your labours are guided by the intelligence that patient study ensures. No matter what your natural aptness may be, you must study and think, and labour.

Most of the great artists of former times were very accomplished men — not mere painters, or sculptors, or architects, but frequently all these combined, and much more. Remember Michael Angelo — painter, sculptor, architect, philosopher, poet! Think of Leonardo da Vinci, and his varied attainments! The wild Benevenuto Cellini could fortify and defend a city, engrave a medal, or cast a statue, with equal facility!

Who among our generation is like one of these?

I remember listening to the discourse of an old French artist, whose acquaintance I made some years since: he was one of those many-sided geniuses who can do all things well. To look at his pictures, you would say, "Ah! here is a great painter!" He would take you into another room and show you a host of exquisite clay models: you would innocently ask "Whose are these charming productions?" and he would say, "The occupation of my hours when not employed in painting." He would then open a portfolio of etchings — the work of his long winter evenings! I cannot stop to swell the catalogue of his various talents. But I remember his words—"In any profession but that of artist it is sufficient to know *one* thing well; but the artist must know all things, and know them all well." This must have been the faith of the great masters.

The artist not only imitates, he transforms — re-creates. You may select twenty artists, all equally clever, and place them before any given object, and request them to make a faithful picture of it. Yet, strange to say, each working conscientiously to the end indicated, no two pictures will be alike! It is the same with the poet: he takes a current thought or idea, and passing it through the laboratory of his mind, transfuses it, informs it with the spirit of his genius, and recreates it. But no other poet will reproduce the same thought in the same terms of expression. You may constantly see the same diversity in the productions of the photographer, mechanical though they appear to be. Yet how easy it is to recognise in the photograph the directing power of an informed hand obeying the educated eye!

P.S.—From your last letter to me, I strongly suspect that my labour in seeking to inform you upon what you are really ignorant, is thrown away. You presume to question and cavil, forsooth! And a letter I have just received from your grandmother, who is in great tribulation about you, confirms my worst suspicions. She says you are never without a short pipe in your mouth, and that she caught you the other morning anointing your upper lip with some of Rowland's macassar oil. The best thing you can do is to put my letters into a preserve jar, seal it carefully down, and bury it in the garden for some seven years. At that date, having gained some wisdom with your last teeth, you may be prepared to appreciate what you now contemn. It is much less trouble to be a mechanical photographer than an artistic one. I do not suppose you will be content to remain long only the former; and perhaps when you have arrived at a proper appreciation of the insignificance of the one and the exaltation of the other, I may resume the subject, and return to an exposition of my views of artistic photography.

Foreign Correspondence.

Paris, October 27, 1859.

I WAS agreeably surprised upon the reception of the number of your Journal for 15th December last, to find described in it so ingenious an actinometer as that proposed by your inventive correspondent and contributor, Mr. Burnett. Our Parisian milliners have a saying, which they often ingeniously quote, to the effect "that nothing is so new as that which is forgotten;" and although I at once remembered having read your description of Mr. Burnett's skilfully contrived apparatus, I confess, to my shame, having entirely forgotten it. I can only account for this *lapsus* by the fact of its being published so near the close of the year, when one is apt to think the year finished, and that anything new should be reserved for the new year. At the present time it possesses much more interest to me than it could have done then, by its connection with M. Nièpce de Saint Victor's researches.

I must at once vindicate that gentleman from the charge of plagiarism. He is so deeply absorbed in his own investigations, that he is likely to share the fate of Archimedes. I doubt if he ever looks into an English journal, and am sure he would never have heard of Mr. Burnett's invention unless I had told him. I fully believe that all he has published respecting uranium is entirely original with himself, and independent of any discoveries or inventions made by others. He is pursuing a path of his own; and if in the course of his researches he arrives at a result previously arrived at by another, the merit of originality is none the less his. Two voyagers may sail from a port, one to the east the, other to the west, and both meet at some distant isle in mid ocean not laid down in our charts, and both may fairly claim the merit of *original* discovery.

I have made many discoveries in science, purely original with myself, but which also occurred to others, in other parts of the world, at about the same time. Thus, during the famous trial of Madame Lafarge, for poisoning her husband, I daily repeated all the experiments made by Orfila and other toxicologists with respect to the detection of arsenic, when I hit upon Reinsch's test without thinking it was original, nor did I discover it was so before I saw it attributed to him. More than twenty years ago I proposed tar as a disinfecting agent, in conjunction with earthy matters, for slaughter houses, &c.; the same thing has recently been proposed by MM. Corne and Deureaux; and I cannot doubt that the discovery is original with them. I know they cannot have plagiarised from myself, because I never thought my suggestion worthy of publication. You will, I am sure, acquit M. Nièpce de Saint Victor of the charge of plagiarism, and give him the credit of being an independent discoverer. I suspect the English journals are not so carefully read in France as the French journals are in England. Nothing that transpires here escapes your keen inquiries, and I may even go so far as to say, that I know better what is going on here, in many things, from perusing your Journal than I could from any other source of information.

Among the recent useful applications of photography, I may instance that of copying tables of logarithms of five decimal places, from one thousand to ten thousand whole numbers. This is suggestive of other useful applications of a similar character, amongst which are photographic visiting cards. This ingenious application of photography is all the rage in Paris. To possess a miniature portrait gallery of one's friends is certainly a great privilege and pleasure; but the indulgence of the taste leads sometimes to amusing adventures. M. V., an eminent dramatic author, found one day upon his table the portrait of a very charming popular actress, whose unblemished reputation rendered the usual reserve of society unnecessary. He carelessly put this portrait card among his own. A few days afterwards our author had occasion to make a call upon a manager, who, being absent, he left, as he thought, his card for him. Next day the manager, who had long desired to attach the charming actress to his company, waited upon her, in the belief that she had called to offer her services. The lady could not understand the manager at all, still less how he could have obtained her portrait. After much perplexity she remembered that she had left her card with the dramatist, and no longer doubted that he had been the cause, innocent or otherwise, of the *imbroglio*.

It is said the manager is willing to give up the lady's portrait on one condition — that of obtaining the original as a member of his company.

M. L. Krafft has communicated to the editor of *La Lumière* an improved method of preparing iodide of ammonium, which is, I think of sufficient importance to lay before your readers. He says, "all the ammoniacal salts by double decomposition with iodide of potassium may be made to yield iodide of ammonium. Dissolve in as little warm water as possible 20 drachms of iodide of potassium, and in another vessel 8 drachms of sulphate of ammonia, also in the least possible quantity of water. Mix the two liquors together, ebullition takes place, and the mixture is left to repose. Upon cooling it deposits crystals of sulphate of potass; the mother waters contain the iodide of ammonium. These must be evaporated under a receiver in presence of sulphuric acid, if it is desired to obtain crystals. It is preferable, however, to take the liquid and add to it the quantity of strong alcohol necessary to form an iodising solution."

Correspondence.

☞ **We are at all times willing to assist our Correspondents to the utmost of our ability, but we can only do so through the medium of the Journal. We cannot give private replies except to personal friends.**

OPTICAL DISCUSSIONS.

To the Editor.

Sir,—Although it requires no small amount of courage to break a lance, especially on a subject of optics, with the Editor of The Photographic Journal, I feel I must enter the lists.

In the editorial note to my letter (page 250), you say, "Opticians have an objection, based upon experience, to transmitting an uncorrected ray for any distance," &c. It is to this doctrine I am going to demur, and I will combat it with experience.

The elements of the posterior lens of a portrait combination are usually *separated* to a greater or less degree; and why? because the results are better — the marginal definition is improved. Cement the back lens and the central definition is no better than when its parts are separated, even so far that the uncorrected ray emerging from the flint concave has to pass a distance of a quarter of an inch before entering the crown to be corrected. This is fact the first.

The second is, that in Petzval's last combination the same principle is carried out. Practically it seems all right, and based on the calculations of such a sound mathematician as Petzval undoubtedly is, cannot be theoretically wrong.

My third fact is, that even in such a delicate instrument as an astronomical telescope, a ray may be allowed to pass uncorrected for a very considerable distance before entering the flint. I myself have, to save the enormous expense of a flint disperser, made such an one: they are now, I believe, extensively manufactured on the Continent. The largest one constructed on this principle, of which I am aware, is that made by Mr. Barlow; the object glass (of *crown* glass) was 7·8 inches in clear aperture, with a focal length of 78 inches. At the great distance of forty inches from this lens is placed the concave disperser, of 59·8 inches focus —parallel rays coming to a focus twelve feet from the outer lens. The telescope bears a power of 700 on the closest double stars in South's and Herschel's catalogue. This latter fact is such a potent one that I need not adduce further evidence to prove that an uncorrected ray may be allowed to travel even a considerable distance.—I am, yours, &c.

81, *South Bridge, Edinburgh.* JOHN TRAILL TAYLOR.

[We perceive that we have been guilty of obscurity of diction in our remarks. The words "any distance" were meant to convey the idea of "any *considerable* distance" which does not apply to the components of the posterior portion of a portrait combination. In this case the film of air between the flint and crown lenses itself forms part of the combination; and the same observation applies to the orthographic form of Professor Petzval's lens.

It would not be possible to cement the back elements of the best portrait combinations nor those of the orthographic lens, for the simple reason that the proximate curves are not identical.

In asserting that "practical opticians have an objection founded on experience to transmitting an uncorrected ray any [considerable] distance," we merely enunciated *a fact* without expressing an opinion whether the objection were well or ill founded; but we may remark that the late Mr. Andrew Ross (no mean authority) was well acquainted with Mr. Barlow's experiments, and had *not* a favourable opinion of the plan.

With practical *astronomy* we are unfortunately but little acquainted, and therefore are personally ignorant as to the severity of the test adduced by you for a refracting telescope objective, 7·8 clear aperture and twelve feet focus. We have, however, had recourse to an astronomical friend, one who stands in the very first rank amongst astronomers, and he says:

"The double stars enumerated in Herschel and South's Catalogue were observed and measured with two instruments, both of *far less aperture* than the 7·8-inch object-glass to which you refer. These stars were measured with two equatorials — one having an object-glass 3¾ inches aperture, and 5 *feet focal* length, by Dollond; the other *a* 5-*inch object*-glass, by Tully, of 7 *feet focal* length: hence the separation of the stars of the above-named catalogue is *not a test* for an object-glass of 7·8-inch aperture and 12 feet focal length; nor is its bearing a magnifying power of 700 a critical test.

"By the subjoined list of the closest stars in Herschel and South's Catalogue, you will perceive that they are not difficult for a telescope which ought to separate equal stars 0″·5 in distance easily on favourable occasions.

		″	
32	Orionis	1·3	
ζ	Orionis	2·62	
57	Cancri	1·89	
ζ	Böotis	1·68	
η	Coronæ	1·57	
σ	Coronæ	1·45	
ζ	Herculis		seen single.
73	Ophiuchi	1·99	
π	Aquilæ	1·96."	

Had you compared with microscopical optics, we should have been quite at home with any test you might have proposed; but in either case we would have you remark, that the requirements in a photographic lens are totally different in a very important particular. With telescopes as with microscopes, the former especially, the *field of view* is limited to a very small angular space, and thus the degree of obliquity of the extreme pencils of rays is but little removed from the direction of the axis of rotation; but with photographic objectives the very reverse is the case. By far the greater number of the pencils of rays employed in producing a picture pass through the lens *much more obliquely* than even the extreme ones of those used in a telescope objective; and it is these oblique rays which suffer most when transmitted any [considerable] distance uncorrected.

We are obliged to you for entering into the discussion; we seek not our own glory, but simple truth, and shall be most ready to acknowledge any error of which we may be convicted. We are not so vain as to imagine that we are infallible; but as we do not adopt opinions without consideration, so also we are not likely to give them up without due reason assigned.

Now to maintain your point with respect to a telescope object glass (setting aside any question of its bearing upon a photographic one), you ought to show that the *definition* of an instrument constructed as described by you, is equal to one of like aperture and focal length, constructed on the ordinary plan. We have no doubt, from what you say, that a *good* telescope may be obtained at a reasonable cost in the manner you describe, but question whether it would be equal in performance to a well manufactured one of the old form of corresponding size.

We think the weight of evidence is against you.—Ed.]

PARAFFINE PAPER PROCESS.

To the Editor.

Sir,—Since my last note, which I thank you for kindly inserting in the Journal, the experiments on the modified waxed-paper process have been occasionally continued; part of the results I now have the pleasure to enclose, with others, for comparison, taken last year by the method stated in my first communication. Iodide of zinc is easily soluble in paraffine oil as in belmontine; gutta percha also in both by gentle heat. With those in the paraffine I have attempted to take some negatives, but do not find any advantage over the original plan. The gutta percha, two grains to the ounce, it is true renders the paper very transparent. The negatives are left unwaxed that you may see the mottled appearance they present, which I expect would be removed on re-waxing. The papers prepared with it and iodide of zinc are less sensitive; they bear the developer well. The iodide of zinc, though furnishing an iodide readily soluble in the paraffine, appears to give a coarse precipitate of iodide of silver after floating on the sensitising solution.

Covering the paper first with a surface of iodised albumen as you suggested, I have, at least temporarily, set aside, owing to the great difficulty of preventing stains and irregular development, which I attribute to the partial displacement of some of the paraffine when floating the prepared papers on the sensitising solution, that leaves a greasy kind of film on the surface of the liquid, which attaches itself strongly to the next paper — and this especially if the papers be not perfectly dry. Enclosed is a well marked negative for your examination. I think of returning to free iodine in the paraffine, and a soluble iodide as potassium sodium, ammonium, or calcium, in the albumen liquid, adding sugar of milk, for I find it assists the development. Perhaps the use of Iceland moss, as suggested in the positive printing process, by Mr. Hardwich, might be still more favourable to density: though this will involve the necessity for re-waxing, it will permit the use of much thinner paper than the generality of the English papers—Marion's and Canson's being those I have hitherto found the best for the purpose.

Pray make any comment on this communication that you may think necessary, for the subject is one of interest, and your remarks are always so practical that they will not fail to attract the attention of yours, &c.

Woolston, Southampton, Oct. 20, 1859. R. L. MADDOX, M.D.

TONING.

To the Editor.

Sir,—As you so frequently recommend Maxwell Lyte's gold toning formula, will you be kind enough just to analyse the description of the process as stated in No. 90, March 15, viz.:—

"The proofs printed darker than required to appear when finished are first laid in a dish of clean water."—Question 1. *How long to soak? in soft or hard water?*

"Then remove to salt and water;" no definite quantity given.—2. *State quantity of salt to quantity of water.*

3. Should the print be placed in the toning bath immediately on removal from the salting bath, or should it not be well washed after the salt bath before immersion in the gold?

"The mixture *should* be neutral."—4. If not neutral, how must it be made so?

"On removal from the bath *(gold)* to be placed in pure water."—5. *Hard or soft? and how long in the water?*

6. "A *fresh* solution of hypo."—Does that imply a fresh portion for each print, *or* how?

"The portion of gold toning used must not be returned to the stock bottle."—7. *How* long may it be used? If put into a bottle by itself, *what indicates* its becoming useless?

Now, if you could give a plain formula for the above process, with all the quantities definitely put down, I think it would be extremely useful to many of your readers.

With my best thanks for previous information, I am, yours, &c.

M. C. C.

[1. Five to ten minutes; soft water if at hand, but it is not very material, the object being to get rid of all free nitrate of silver.

2. Not important — a saltspoonful of salt to a quart of water answers well.

3. It is as well to rinse it after the salt and water bath before putting it into the gold bath, under any circumstances; but if intended to be kept for any lengthened time before going into the gold bath, it is absolutely necessary to prevent the half-tones being injured.

4. By adding to the acid gold solution one of *carbonate of soda,* until litmus paper is no longer reddened.

5. Soft water preferable. A few minutes, say five.

6. Not for each print, but for each occasion when used — that is, if you tone and fix a dozen prints, one after another, the same bath will do (provided it contains enough hyposulphite of soda to dissolve out the silver); but if used to fix one print only to-day, the same bath should not be employed to fix even one to-morrow; because, after use, the bath contains *hyposulphite of silver,* which brings about decomposition in the bath, if kept.

7. Until it no longer tones. Generally a day or two after use, a dark coloured deposit will be found in the bottle, in which case the liquid is useless, the gold having been all precipitated. It is not difficult however to use a fresh quantity for each print, and this without waste, if you remember that *a grain of gold* salt will tone thoroughly a full sheet $22\frac{1}{2} \times 17\frac{1}{2}$ inches. The quantity of bath measured out may be expanded by the addition of water to a convenient working quantity. Provided the requisite quantity of gold be present, the actual *strength* is not of much consequence, though it may influence somewhat the rapidity of the operation. —Ed.]

FORMULÆ—CONVERTING POSITIVES INTO NEGATIVES.

To the Editor.

Sir,—The valuable communication of M. Blanchere, on *cadmium* in collodion, in your *last* number, is *lost* to *many amateurs,* by the quantities being expressed as 7·50 drachms, &c., &c., 0·25, &c., instead of *plain English.* Many beginners and others are *ignorant* of these symbols. Would you kindly explain.

I find a *positive* can be converted into a *negative* by *re*developing with pyrogallic acid *after* the *usual iron* developer and cyanide fixing process: in the daylight the negatives thus produced prints well; is this usual?

An answer will oblige, yours, &c. SUBSCRIBER.

October 26, 1859.

[We were under the impiresson that the formulæ given were in *very plain English.*

The quantities are stated in decimal instead of vulgar fractions, for convenience of addition.

7·50 drachms means seven drachms and fifty hundredths, or seven and a-half drachms; and 0·25 drachms twenty-five hundredths, *or a quarter of a drachm.*—Ed.]

ANSWERS TO CORRESPONDENTS.

Rustic.—Send a directed envelope.

H. Meigs, Boston.—You will find the formula in No. 98 of this Journal.

Emma C.—Thirty-six centimetres by twenty-eight is equal to fourteen inches by eleven, very nearly.

Secundem Artem.—See Mr. Wall's articles on colouring; and if you have any difficulty, write to him, as notified at the end of his paper.

Omega.— Your questions have been repeatedly answered in this Journal: refer to the back numbers.

T. B.— We cannot promise a *favourable* review — that must depend *entirely* upon the merit of the production. We submit to no conditions.

Crayon.— At present photographic engraving looks more promising when executed on stone than on steel; in the latter there is a dull opacity in the shadows which greatly mars the artistic effect.

Nil Desperandum.—The twin lens camera unquestionably. Send a directed envelope, and we will endeavour to supply the other information required.

Benzoin.— If the lac does not readily dissolve place the bottle containing the spirit and the resin in warm water, or before the fire, but not too near.

B. Foster, Diss.— It will be necessary for you to obtain a "copying camera:" any cabinet maker will make you one upon receiving proper instructions.

M. M.— No portfolios we have ever seen are so good in every respect for preserving photographs as those invented by Harvey, 16, Rathbone Place, W.C.

R. Salter, Ipswich.—We believe the exhibition will be opened early in January next, so you will have ample time to prepare your specimens for it.

Pyroxyline.— There ought to be no difficulty in obtaining a good collodion now-a-days; but you may spoil the best that ever was made by carelessness or injudiciously tampering with it.

Sat. Sol.— There is no substitute for hyposulphite of soda for fixing positive proofs that will answer so effectually. It is to be hoped that one may be discovered.

Experimentalist.— Use Maxwell Lyte's gold toning formula and a foreign paper to obtain violet tones, or an English paper for brown or black shade. The different nature of the sizing influences the result, but *not* the salting material.

Black Tips.—You may remove the stains without cyanide of potassium thus, viz.:—touch the stains with tincture of iodine, and let them dry — then use strong solution of iodide of potassium; do this alternately till the blackamoor is washed white.

Steph. King, Mansfield.—The best salting material for positive paper is unquestionably chloride of ammonium, to which a few drops of *liquor ammonia* are added to neutralise any acid that may be present. You had better float your paper on a mixture of equal parts albumen and water, and dry the paper, when floated, as quickly as possible.

Cyanos.— Cyanide of iodine consists of one equivalent of cyanogen and one equivalent of iodine. It is always produced when a liquid containing cyanide of potassium is mixed with pure iodine. It was proposed some time ago, by M. Humbert de Molard, for fixing positive proofs. It is a very dangerous compound, and as we can do very well without it you had better have nothing to do with it.

R. R * * * s.—We are obliged for the kind feeling which dictated your communication. Although we certainly have no reason to spare the writer alluded to, we cannot publish your letter for two or three reasons. 1. We will *not* notice an insult that in itself proves the perpetrator to be devoid of all self-respect. 2. We do not care to bore our readers with our own annoyances. 3. We should be following a very bad example. 4. Your article is very caustic, and *too true* to be borne with equanimity by the victim.

H. Baldock, St. Ives.—It is impossible to say what alterations are required in the lighting of your portrait gallery without inspecting it. Proceed methodically in the arrangement of your screens. The effect you desire to obtain is that of good *chiaroscuro;* without it you certainly will never obtain a good effective portrait. The flatness you describe is due to a want of difference in the amount of light on opposite sides of the sitter: one side should be darker than the other. Illuminate one side with direct light, and the other by light reflected from a dull white curtain or screen.

T. A. Morris — Your wishes respecting the copy of the Journal shall be communicated to the person who has charge of that matter. Respecting the stereographs sent, they are all more or less *under*-exposed; but No. 1, which you call "fogged," is by far the best of the three. It is not "fogged," but there is some little indistinctness in consequence of movement of the figures, and in some cases change in position between the times of taking the first and second impression of each pair. This is one strong argument in favour of the bi-lens camera. No. 3 is second in quality, while No. 2 is very much underdone. You should give longer time for exposure, and we think you would find better results arrived at by adding about *one* grain of bromide of cadmium to each ounce of your collodion.

We are not acquainted with the *commercial* value of negatives, but your positive proofs would not be regarded, in London, as of any value at all, they being all more or less defective. You have mounted the two pictures of No. 1 too far apart.

The particulars at the back of each are useful where they are for circulation amongst novices, but of no general utility.

*** Owing to a press of matter we have been compelled to leave over till our next number the conclusion of the "Glossary," some important communications, and several advertisements.

☞ *All* Editorial *Communications,* Books for Review, *&c., should be forwarded to the Editor,* GEORGE SHADBOLT, 2, *Upper Hornsey Rise, London, N.*

All Advertisements *and* Letters *on the* Business *of this* Journal, *should be addressed to the* Publisher, 32, *Castle Street, Liverpool.*

THE PHOTOGRAPHIC JOURNAL.

No. 106, Vol. VI.—NOVEMBER 15, 1859.

It would be a pleasing novelty in the history of prize-giving if it could be truly affirmed that the awards made had given universal or even general satisfaction. We fear, however, that heartburnings are inherent in the system; and did we desire to ascertain the course most likely to encourage "hatred, malice, and all uncharitableness," we should probably find it in the offer of rewards for the supposed encouragement of something else. We have so frequently observed this result to occur, that we do not wonder at finding that it has happened amongst some of the candidates for the smaller prize offered by the Duc de Luynes, for the best permanent method of printing photographs, lately awarded by the authorities of the French Photographic Society.

It will no doubt be remembered that, after having examined the various schemes laid before it, the committee charged with the award determined to test the respective merits of certain of them selected for more precise investigation, by calling upon the propounders of the several plans to operate in producing proofs before the members of the committee, as affording the best possible test of the feasibility of the processes proposed—such foreign candidates as there were having their written directions carried out by skilful manipulators amongst the members of the committee.

The conclusion arrived at was, that none of the candidates were deemed worthy to receive the entire prize, which, however, with the consent of the donor, was divided amongst five or six in the form of gold medals. As might have been foreseen, such a decision has by no means given satisfaction; and certain of the candidates, Messrs. Salmon and Garnier, have gone the length of serving the authorities of the French Photographic Society with something like a legal protest—not *nominally* against the award it is true, but for having divulged the details of the process employed by those gentlemen, although one of the conditions required of *candidates* for the prize was an unreserved publicity.

In noticing this matter we take the opportunity of again suggesting what we believe to be the only sound principle of affording to photography encouragement by presenting prizes, viz.—that of distinguishing eminent services or peculiar excellence in manipulative, artistic, or scientific skill, by the presentation of something by way of *acknowledgment*—and not as a reward to the most successful amongst *competing* candidates—wherever and whenever unusual excellence may be displayed, without regard to competition.

To illustrate our meaning more clearly, we will put a suppositious case. A Society having a given income determines to set aside a certain amount each year to be distributed in the form of prizes. Suppose, for instance, the Photographic Society should determine to devote an annual sum of say £50 for this purpose. After the close of each session a well-selected sub-committee should be appointed to review the proceedings of the past year, and consider, 1st, Whether any new and important principle had been introduced into any branch of the art, and if so, by whom? 2nd, Whether any obscurity in the phenomena known to exist had been cleared up, *e.g.*, the cause of fading, &c.? 3rd, Whether any pictures at the Society's Exhibition were pre-eminently distinguished for artistic excellence, combined with manipulative skill, &c.? 4th, Whether any important improvement in apparatus, &c., had been introduced? If under any or all of these heads it should be found some cases were peculiarly worthy of note, it should be the duty of the said sub-committee to *recommend to the Council of the Society* that certain individuals, instrumental in their introduction, should be presented with some appropriate acknowledgment.

The Council of the Society should then decide upon the expediency of carrying out the recommendation in each case, and the nature of the presentation to be made.

In the event of there not having been anything during the year deemed worthy of special recognition, the funds not so employed might be added to those for the succeeding year, and so on, until an unusually heavy demand upon them might arise.

Successful competition *alone* can never be a fair test of merit. Before this can be conceded, the number and qualifications of the candidates must be taken into consideration: the *best* might in some cases be very mediocre, whilst in others even the worst might be meritorious. By such an arrangement as we have supposed, most of the evils of prize distribution would be avoided while any advantages would be retained; and under the scheme we have sketched, every one who might have contributed to the advancement of the art, whether by furnishing papers read at the meetings, or by oral communication, or by pictures, or apparatus exhibited, &c., would have a fair chance of a recognition of his services.

We commend to the consideration of the Council of the Photographic Society the letter of an anonymous correspondent which we publish in another column. The first meeting for the session (a report of which will be found in the usual place) was certainly anything but creditable to the managers of the Society, and far from complimentary to its distinguished President, to whom every acknowledgment is due for the kind interest he takes in its welfare. At his time of life there are not many others whose duties are so laborious, whose elevated positions have been for so long a time attained, and yet who would have taken the trouble, on a bleak November evening, of leaving their comfortable fireside to preside at any meeting, much less at an abortive one. We should not have remarked upon this subject, perhaps, had not our attention been specially directed thereto by the letter from an *old member* of the Society. But we allude particularly to the meeting, in consequence of the announcement made by the Secretary, relative to the alleged solution of the problem of carbon printing, by M. Joubert. It may appear premature to express our want of faith in the fulfilment of the promises held out; yet we must confess to strong misgivings on the subject, and these are chiefly induced from the wording of the letter that was read from M. Joubert. The most perfect copy of an engraving that can be attained *is no solution of the difficulty*, there being no true half tones therein: the middle tints of a photograph, which constitute some of its principal charms, have hitherto proved the stumbling-block of carbon printing; and, from the absence of any remarks on this important particular in the letter, coupled with the marked stress laid on the wonderfully accurate imitation of an original engraving, we infer that but little real advance has been made. By the time

these words reach our readers we shall probably be in a condition to judge more correctly than we can at present pretend to do.

But upon carbon printing proper we have somewhat to observe. We have for some time entertained an embryo scheme, founded upon one of the photo-lithographic processes, but which, from our want of familiarity with the printing part of lithography, coupled with the constant occupation of our time, we have hitherto been unable to put to the test.

It is found that printing-ink will adhere to the gelatine, hardened by actinic action under the influence of bichromate of potash. In some of the ink-printing processes, albumenised-paper has been employed in conjunction with an alkaline bichromate, and when the unaltered bichromate has been washed out of the paper, the albumen *has been removed* from those parts not impressed by exposure. In one of the patent lithographic processes the stone is prepared with a mixture of gelatine and bichromate of potash, the impression made under a negative in the usual way, the unaltered mixture removed by washing, and the image rendered visible on the stone, by passing an inking roller over it while still wet — the ink adhering to the hardened gelatine. We remember hearing Mr. Pouncy say, with reference to this patent, that the process was a failure, in consequence of the ink *breaking away* from the stone in the subsequent operation of working off the proofs, and this because the ink was not actually on the stone but only adherent to the gelatine thereon.

On thinking over our printing scheme, our plan was to proceed as follows: — A sheet of albumenised-paper to be floated on a saturated solution of bichromate of potash, either with or without the addition of oxalic acid (the latter hint we took from Mr. Burnett); this to be exposed for a few minutes under a negative, and then thoroughly washed; the impression would then appear of a buff tint, glossy in the shadows because of the albumen, but dull in the lights, from which it will have been washed away. While still wet it is to be laid upon a sheet of plate-glass or smooth slate, face upwards, and pressed lightly with a sheet of blotting paper to remove surface moisture, and then a printing roller charged with ink to be immediately passed lightly over it. As the paper would be in a condition precisely similar to that of the lithographic stone, the albumen being substituted for the gelatine, we expect that the ink would adhere to that part, and be repelled by the lights which would be saturated with moisture.

As we have already stated, we have had no opportunity of putting this idea into actual practice; but while we have been dreaming over it, a French photographer, M. Asser, seems to have hit upon an analogous method of operation, and, what is more mortifying to us, has actually put it into practice, as we are informed.

He is said to have employed unsized paper, to have coated it with starch, and then treated it much in the same way as that we had proposed to do — only that with starch it is needful to be more careful with the washing, and to dry and *heat* the proof and again moisten it *prior* to inking. He also mixes a little *varnish* of some kind with the printing-ink.

Our own scheme would be the simpler of the two if found successful in practice. We wish that some of our energetic readers would try it; but be the result what it may, M. Asser has certainly anticipated us in publication, and we shall have lost all claim to any of the honour that might possibly have accrued. We are forcibly reminded of our school days, when we used to write in round hand

"PROCRASTINATION IS THE THIEF OF TIME."

We have little doubt that, simultaneously with the publication of the present number of The Photographic Journal the regulations relative to the forthcoming exhibition of the Photographic Society will appear in its own organ; but as there are not a few of our readers who do not see that publication, we beg to remind them, that it has already been notified that the contemplated exhibition will be opened in Pall Mall early in January next, and that consequently contributions will be required to be sent in at about Christmas time. Those intending to send specimens will therefore do well to prepare them.

This would be a valuable opportunity for the comparison of the results of the various dry processes: we feel convinced that those who have the arrangement of the pictures would hang *together* the specimens intended for such illustration if so requested. But in order to accomplish this end more certainly, and with as little trouble as possible to the hanging committee (and only those who have tried it can know how extremely necessary it is to lighten the work as much as possible), we would suggest that labels should be attached to some part of the *front* of the specimens intended for the purpose, bearing the words following, written in legible characters, viz.—" Illustrative of the ——— Process," the blank of course being filled up by the name of the process employed.

PHOTOGRAPHIC CONTRIBUTIONS TO SCIENCE.

It appears to be a singular freak of nature that the offspring of parents, diverse in their kind, sometimes inherits the vices of both progenitors, whilst in other cases all the good points of each seem to centre in the same favoured individual. In this latter category we may class photography, the child of science and of art.

We have on several previous occasions had to make favourable mention of certain contributions to what we regard as its maternal parent, ART, for which we have been indebted to that infant Hercules — Photography: we have now to direct attention to another boon, in the shape of a valuable contribution to its paternal progenitor, SCIENCE.

Many as have been the advantages which science has derived from this new aid to its powers, it is only here and there that the *utile* and the *dulce* have been so harmoniously combined as in the case to which we are about to allude, in which photography and stereography play an equally important part.

Some of our readers have doubtless, by M. Ferrier's aid, been enabled to climb the mountain passes of the Swiss Alps, and feast their eyes on glittering glaciers. Mr. Piazzi Smythe has rendered accessible the lofty regions of the Peak of Teneriffe, and brought down for quiet inspection in our homes the marvellous dragon-tree. Messrs. Negretti and Zambra, the official photographers to the Crystal Palace Company, have some time since had a gentleman in their service, who has been devoting his energies to the delineation of subjects of considerable interest in China, some of which we noticed casually in our report of a *soirée*, given by the Lord Mayor at the early part of the present year.

In the Pacific Ocean there exists a mass of islands, known as the Indian Archipelago, the northernmost group of which, the Philippines, is a dependency of Spain. Of this group the largest island has an area of something less than 60,000 square miles, its greatest length being not much shorter than that of Great Britain, though considerably less in breadth, especially at the centre, which in fact is nothing but an isthmus, nearly fifty miles long and about twelve broad, connecting the northern and southern portions of the island, which bears the name of Luzon. The whole island is more or less mountainous, and amongst the mountains are several that are volcanic, one of which, the Taal, is somewhat singularly located, being in the *middle of a lake.* To this volcano the enterprising photographer wended his way, according to instructions received from Messrs. Negretti and Zambra, incited thereto by some zealous geologists who were anxious to pay a visit to the spot in such a convenient manner by deputy; and, having been there, he brought away with him that for which he went — an exact transcript of the crater.

We cannot forbear laying before our readers the following extract, so full of interest, from a letter received by Messrs. Negretti and Zambra from their representative:—

The Taal Volcano, in Manilla, is situated in the middle of a lake; the circumference of the crater is probably half a league.

According to your instructions I started from Canton and proceeded to the Philippines. Arrived at Manilla, I went on to the village of Taal, from thence on to the crater. I left the village at midnight and got to the spot at eight in the morning, travelling by canoe. Arrived at the edge of the crater, I pitched my tent; but such was the heat of the place, and *so dense the steam that arose* from the fissures, that I was glad to move further off to avoid being suffocated. Having found a more convenient spot I tried my first plate; nothing! second, ditto; third, fourth — all black, all over-done: suffice it to say, that though I had been giving from thirty to forty seconds, with same light and same chemicals, the day before, I obtained the negatives I send you with *four seconds'* exposure — a curious circumstance deserving investigation.

I was surrounded with sulphurous vapour, more especially when the wind (which was continually shifting) was blowing towards me: such was the density of the vapour, that on one occasion indeed my two guides bundled into my tent, to the great danger of my bath and chemicals.

I send you the three negatives I was enabled to take, and would have gladly sent you duplicates, but after about a couple of hours' work my bath got covered with a black pellicle which adhered to the collodion, causing the plates to stain all over, so I was obliged to give up.

On the north-east of the small crater you will see a small lake: its waters are covered with a white vapour like steam; its borders strewed with a greenish white sulphurous substance, caked like ice on the edge of a pond. The effect all along the edge of the lake is very curious. I attempted to descend from the great crater to the inner one, in order to follow your instructions as to the temperature and density of the water; but I felt so weak from excessive perspiration that I was obliged to desist: it has to be done by a rope. I however sent down one of my guides who brought up a gourd full of water, the temperature of which, was, when I received it, 110° Fahrenheit. I will send it to you if I have no accident, as it might be interesting to some of your scientific friends.

I left the crater about twelve o'clock, and returned to Taal by half-past-five, having wind and current in my favour. I have already told you of many difficulties I had, especially in Canton; but this volcano photographing beats all. I sincerely hope your friends will not suggest any more such interesting objects for your photographer to take. As to Japan, I have no doubt I shall get on very well but if I hear that a volcano exists there I shall be tempted to turn back, as I think one volcano in my life will be sufficient.

Three admirably-printed glass transparent stereographs, from the negatives mentioned in the above extract, are before us, and anything of the kind more interesting it is not easy to conceive of. Very few of us have had the opportunity of taking a peep into the crater of any volcano: what a privilege we ought then to regard the power of looking into one upon such easy terms, and that one of such an unusually interesting character!

In one of the slides, the smaller inner crater, with the smoke issuing from it, is visible, together with the hot-water lake mentioned in the letter; while far away, over the further edge of the large crater, are seen the more distant mountain ridges, and in another the waters of the mighty deep.

It will readily be acknowledged that the production of such specimens is no ordinary task, whether we regard the distance of the locality, the difficulty and expense of reaching it, and lastly, the severe expenditure of labour and strength requisite to procure the negatives when there—the value of which, in a scientific point of view, is scarcely calculable.

We sincerely trust that Messrs. Negretti and Zambra will meet with the encouragement they so richly merit, by an extensive demand for these highly instructive and interesting subjects, and thereby be induced to renew their efforts for placing before the public specimens so well calculated to elevate the taste and inform the mind.

CONTROVERSY RELATIVE TO THE SWING-BACK CAMERA.

REPLY TO OUR CHALLENGE.

By N. Ennel.

In No. 99 of your valuable Journal I found, at page 184, the article alleging to deny the correctness of my observations in the *Journal of the Photographic Society*, with regard to the swing-back. I truly regret that I was, till lately, ignorant of this article, or I would have replied to it immediately after its appearance.

I must confess I feel rather puzzled to know how to shape the course of the argument after so clever a feint of yours in knocking down my premises like nine-pins, without saying why. You merely *cannot* assent to the premises, nor, of course, to the conclusion. Suppose we put the case in the form of a syllogism:—

All circles projected on an inclined plane are ellipses.* (Major premise).

The back of a camera not parallel with the front is an inclined plane. (Minor premise).

Therefore, every image produced on the swing-back is distorted. (Conclusion).

Can you detect here any fallacy?

But I must not forget that you ask for a *nicer* definition of "*every point*," and of "*distortion*." I thought these terms plain enough, and had not given any definition; but in deference to you, who think otherwise, I will say that by *points* I do not mean mathematical points, but visible forms, with certain proportions, as perceived naturally and in conformity with certain laws of perspective; and by *distortion* I understand a false representation of these forms, *i.e.*, a representation in which the relative proportions differ from those of the original. These definitions, I trust, you will not find dogmatical, seeing that I use the terms not in a particular but general sense, and in the common acceptation of the words. *Distortion* must not be attributed to a medium only, but be acknowledged wheresoever found, without reference to its cause; let the cause be, as in the case before us, the disturbance of the parallelism between lens and back.

Having cleared the way thus far, I will proceed to show that, in spite of yourself, you have, in fact, assented to my proposition. You admit that in the case of a small distant window the swinging back would be *misapplied*. Why? Because the window would be misrepresented; instead of appearing, *e.g.*, a square, or a circle, it would be an oblong or an ellipse. Pray hold this fast. Let this little distant window be in a high tower, or in one of the houses on the one side of the street; focus it. The swing-back here, by your own admission, would be *misapplied*. Now you want to bring also into focus the more distant windows, and likewise the nearer ones of the tower or street; you swing the back, and at the same time you have distorted, at all events, *that little window you first focussed*. Now, you cannot surely admit this, as you must do, and as you have done, and deny the corollary that the next window, and the next to that, &c., are distorted! Or imagine the whole tower, or the whole side of the street, one huge window. If the proportions (or, as you say, *scales*) of a *small* window are not truly represented on the inclined plane, the disproportion of the large window must only be all the more obvious! In a word, your high tower and every detail of it will appear too *high*, your street too *long*, and every house in it, and the details too *wide* in proportion. But you go even further; you grant that "*the scales differing is an error*, but only an error of degree." Now, really, in a scientific point of view, is not "*error*" synonymous with "*wrong in principle?*"

[It will be perceived from the preceding how necessary it was to ask for *nicer* definition of the terms *points* and *distortion*. We demur to the interpretation of the former word, as we require it in its strict sense for our rejoinder; we propose to substitute the word *parts* to indicate Mr. Ennel's meaning. We shall abstain from detailed reply till our next — partly to give Mr. Ennel every chance of a fair hearing, and partly because we have no space to spare in the present number. We may, however, remark that we dissent quite as much as before from both premises and conclusions.—Ed.]

NEW STEREOSCOPIC CAMERA.

By R. L. Maddox, M.D.

The accompanying diagrams will, I trust, render intelligible the purport of this communication. It looks complicated, but is not so in reality. It may interest some of your readers, though without a sketch it would not be understood. The intention is to combine in a small space a stereoscopic, portrait, and view camera, with a draw of seven inches.

The mode of using it is with a dark bag, fastened over the back of the camera by a strong elastic band, and with two apertures at the sides, fitted with elastic, to admit the hands, closing tightly round the wrists.

The frame-door *h g* is raised to introduce the screen, and *g* closed on it to keep it in place: removing the screen the frame and door *h g* are held up to introduce a prepared plate, and closed together on it, to keep it in position.

* Being transverse sections of a cylinder that are not perpendicular upon the axis.

In the stereoscopic camera the draw-box, or inner part of camera, is flush with the outer or front edge of *a*, the part *n n* being attached to the second only, to save space.

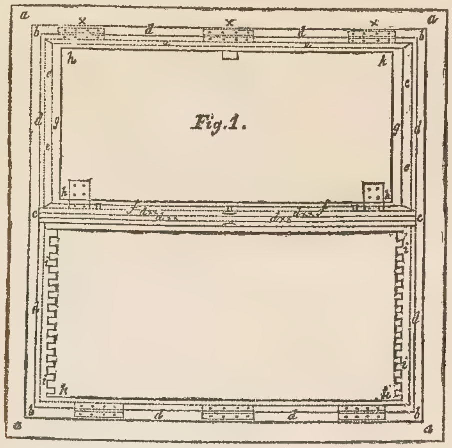


Fig. 1. Front view of outer and inner camera boxes, containing in the lower half the box for prepared plates.

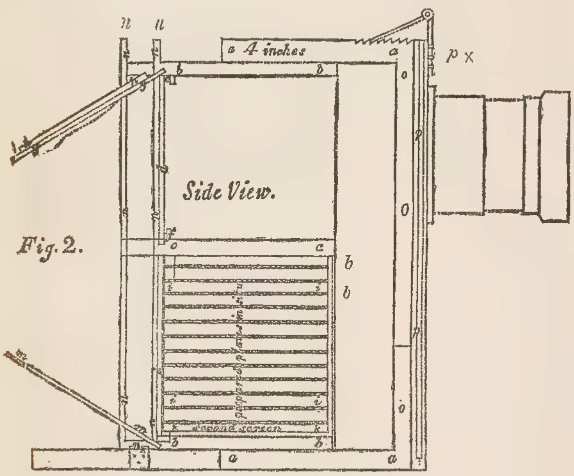


a the outside box of camera, outside measurement 8$\frac{3}{8}$ inches square, made of $\frac{3}{8}$ths mahogany, or other wood; *b* the inner box of camera, to fit into *a*, made of $\frac{1}{4}$-inch mahogany, cut away at its inner edge for the $\frac{1}{8}$th of an inch all round as marked at *d*, and $\frac{1}{8}$th deep, and closed at back *b b* (fig. 2); *c* a flat piece of mahogany to slide in *b*, $\frac{3}{16}$-inch thick, and cut away at its front edge above and beneath $\frac{1}{16}$-inch, as marked at *d*** (fig. 1.), and $\frac{1}{8}$th deep; *e* thin pieces of wood fastened round the top and right and left-hand sides of upper half of inner box *b*, at $\frac{3}{8}$-inch from the outer edge; *f* a thin piece screwed or nailed to upper surface of *c*, at $\frac{3}{8}$-inch from upper outer edge, *g* upper door, consisting of a hollow frame hinged at front edge of *b*, and shutting tightly against the part cut away at the inner edge of *b*, leaving space between it and the thin pieces of wood *e* for the focussing glass or slides to be interposed; *h* a flap door that fits on the frame door *g*, hinged to fall downwards, and so admit of using the focussing screen, and shut tightly when a glass slide is introduced in the place of the screen; *i* small thin box, holding twelve prepared plates, and extra ground glass at *k*; *m* door to lower half of camera (fig. 2); *n** brass guide (fig. 2); *o* space for using a larger lens, to be attached to another front sliding door *p*, kept in position by some contrivance when raised, as *p**.

The whole of inner box removes entirely from the camera, to be replaced by another made on ordinary plan, attached to *n n*, where the screen and dark slides are placed for views or portraiture (fig. 2), unless it be preferred to have but one draw box and make the top and bottom doors, centre division *c c*, the part *b b* of lower half, and the plate box removeable, when one would suffice; this could be done by slight alterations in the measurements, or in hanging the doors differently, as by pins at the side.

Woolston, October 19, 1859.

TONING POSITIVE PRINTS.

By John Heywood.

[Read at a meeting of the Chorlton Photographic Association, November 9, 1859.]

The printing of paper positives has had some attention from me of late; and, as some gentlemen of this Society may have to print a few proofs occasionally, it may not be uninteresting to them if I briefly state the method which I find both economical, and producing results as beautiful as can be obtained by more expensive modes of toning. I use a solution for sensitising the paper, made of a sixty-grain solution of nitrate of silver to the ounce of pure water; to which I add a few drops of acetic acid (say ten minims to six ounces of solution); float the paper for five minutes, then hang up to dry in the dark, catching the drops. These papers will keep in a dark cellar for two or three days. Expose in the pressure-frame, and print very deeply; lay in water when printed, and after you have finished printing for the day, wash all in one tray for half-an-hour, and put the washing water into a large Winchester quart bottle, containing some common salt, to precipitate the silver in the form of chloride, by way of saving any waste; then wash the prints again in running water one-quarter to half-an-hour, put in strong salt and water (say half water and half saturated solution), and wash for five minutes; then rinse in water, and lay the print on a glass the full size of the paper; after draining, brush on the toning solution with a large soft brush, prepared thus:—

No. 1.

Bicarbonate of soda	5 grains.
Pure water	1 ounce.

or

No. 2.

Borax	120 grains.
Chloride of sodium (P.L. strength)	20 to 40 minims.
Pure water	2 ounces.

No. 3.

Another bottle, to contain solution chloride of gold.

Chloride of gold	1 grain.
Pure water	1 ounce.

Mix one minim of No. 3 with five minims of No. 1 or seven minims of No. 2 for each stereoscopic print. A stronger or weaker solution may be used; but a longer or shorter time will be required to produce the desired tone. I generally let the solution lie on until all redness is gone and a rich purple has taken its place; but this is a matter of taste. Two or three pictures may be in operation at one time, and as they acquire the desired tone, be placed in water to await the fixing solution, or they may be placed there at once.

I make a saturated solution of hypo, and take one measure, to which I add two measures of ordinary water, and let the prints remain half an hour. Should old hypo be used, or the immersion be too short, chloride of silver will remain, and on exposure to light the prints will change to a disagreeable dirty colour. When this operation is properly performed, the prints are of a pure white in the lights, and a clear purple-black in the shadows; but the tone is slightly varied by using No. 1 or No. 2 toning solution, and may be increased in depth by more printing, or a stronger nitrate of silver sensitising solution, which should be kept up in quantity by adding sufficient of an 80-grain solution. The prints now require washing; and as there may be doubts as to the time necessary, I lay before you the result of an experiment made in January last. The print was put entire into a bowl of running water, and pieces cut off at the expiration of one hour, at two hours, at three hours, at three-and-three-quarters, and at four-and-a-half hours; the pieces were then mounted in their original positions, and I think you will perceive no difference as regards the washing in any of them. The mount has been exposed for some months to the summer light, and has had more rough usage than pictures that are esteemed would be liable to. I think we may now say that, with ordinary care, our prints will not fade away as they did not very long ago. The expense of a toning bath, where it can only be used for a few days, is rather considerable to amateurs; but by using the toning solution as I have described, you have no reduction going on except with what you are using, and you obtain a tone which is impossible by employing an old bath. To make it more evident, I

have two prints here ready washed, and I shall now proceed to apply the toning solutions No. 1 and No. 2, that you may see the difference in them. I have collected these formulæ from several sources, and claim no originality in any way. To several I am indebted for hints; I would thank those gentlemen. If any one requires information that I have omitted, I shall be very glad to afford it after the toning is finished.

CARBON PRINTING IN LITHOGRAPHIC AND PRINTING INKS.

By M. Asser, of Amsterdam.

Preliminary Observations.

Unsized paper, by its porosity, is readily imbued with water throughout its entire substance.

Those portions of the same paper upon which bichromate of potash, submitted to the action of light, are found, cannot be moistened.

Bichromate of potash, acted upon by light, and warmed at a high temperature, readily receives and retains printing ink.

Unsized paper, impressed with a picture formed by bichromate of potash strongly heated, and then moistened, may be inked like a lithographic stone, in this way:—the non-impressed parts remaining moist, reject the ink, while the impressed parts receive the ink, retain it, and permit of its being accumulated according to the degree of vigour and intensity desired. In substituting printing ink for transfer lithographic ink, we form a *cliché* or negative upon paper, which may be transferred to stone or metal by means of the autographic press. The image now reversed becomes right again when printed.

Unsized paper, covered with starch upon the side impressed with the image, has more stability to withstand the inking process, and is easier to remove about.

Special Process.

Take unsized paper, of medium thickness, and as even a texture as possible: plate paper answers very well—it is prepared specially for engravers. When the sheet is cut to the required size, mark the smoothest side, and then imbue it with an even coating of starch by means of a sponge. Suspend the paper by one corner to dry.

It is not absolutely necessary to starch the paper, but it is preferable, for the reasons specified in the preliminary remarks.

Float the paper, when dried, the starched side upwards, upon a concentrated solution of bichromate of potash in distilled water. The paper immediately imbibes this solution; it is then hung up in a dark room to dry, placing a piece of bibulous paper at the lower corner, to facilitate the dripping of the fluid.

When the paper is perfectly dry, place it, with an ordinary negative, in a printing-frame so as to produce a picture on the starched side. It is desirable that the negative be very sharp and vigorous, without deficiency of transparency.

At the expiration of a given time, which varies according to the intensity of the light and the transparency of the negative, remove the paper from the printing-frame when it appears to be sufficiently impressed with a reddish-brown picture, while the unimpressed parts retain a fine orange-yellow colour; then immerse it in a dish of clean water, image upwards, and remove any bubbles that may form between the paper and the water.

It must be allowed to remain in the water, covered so as to protect it from the light, until all the bichromate of potash, not acted upon by the light, is dissolved out, and until the paper exhibits a very clear image of a light brown colour. Withdraw it from the water and hang it up to drain and dry, and then place it on a piece of marble, heated as high as possible short of scorching the paper. The paper can then be smoothed with a flat iron or in a rolling-press.

This heating is an important element of success, as stated in the preliminary remarks.

Next moisten a sheet of unsized paper, cut to dimensions a little smaller than those of the impressed sheet, and lay it smoothly on a glass plate, and remove the excess of moisture with a piece of bibulous paper.

This done, float the impressed sheet for a few moments upon clean water, the image uppermost, until it is thought that the water has penetrated the texture of the paper and softened the starch. Then remove it from the water and place it upon the moistened paper on the glass plate, and lay over it a piece of sized paper, and rub it firmly all over with a handkerchief, to make the moisture penetrate those parts where the whites remain intact, and to make the impressed sheet and the moist paper upon which it rests, adhere more strongly to the glass; then remove the sized paper so as to display the picture. Previous to this operation an inking-roller must be charged with lithographic ink, mixed with a small quantity of varnish — too much will cause the experiment to fail; it is then passed lightly over the paper which has been exposed to the light, and the image soon begins to appear, becoming stronger with each application of the roller, in the same way as if a lithographic stone was submitted to this operation; and while it increases in intensity the whites retain their purity. If the first application of ink is successful, the image can be strengthened without fear by adding a little more varnish to the ink.

When the picture is sufficiently strong, float it in pure water, acidulated with a few drops of nitric acid, with the view of removing all the bichromate of potash and to leave only the ink. When dried the positive is ready.

If lithographic ink has been employed the design can be at once transferred to the lithographic stone or zinc plate. In that case, the picture must not be too highly charged with ink, and spread very uniformly, and the washing in acidulated water must be omitted. The transfer is easily performed when the paper is damp, not wet, so that the starch may attach itself to the surface of the stone or metal under the lithographic press. If the picture be very highly sized, it can be raised without accident, leaving the impression on the stone or metal, from which any number of copies may be printed. If it require retouching, it can easily be executed. It will be seen that for engraving on metal the system requires that he begin with a positive on glass; this supplies a negative on paper, which transfers as a negative to the metal from which positives are printed.

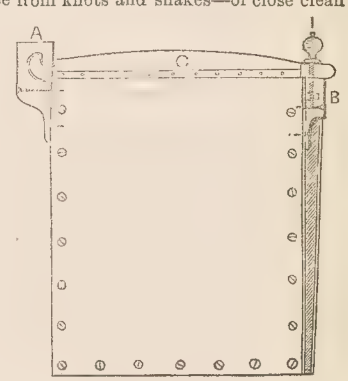
PHOTOGRAPHERS THEIR OWN ARTIFICERS.

By Thomas Gulliver.

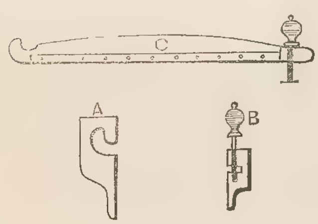
No. II.

WATER-TIGHT WASHING BATH, CAMERA STAND, &c.

The tent described in No. 104 of the Journal will require some special fittings, which, with ordinary care and attention, can be easily made. But first a word or two respecting the selection of wood. Yellow pine will be about the best for all purposes, and should be quite dry and free from knots and shakes—of close clean fibre, and of a pinky tinge (about the first and second leaf from the slab or outside piece of the "baulk" should be chosen). ⅜ inch and ½ inch stuff, *when planed*, will be thick enough for most of the work.



The washing bath should be 10½ inches deep, by 7⅝ inches wide, ⅞ inch at the bottom and 1⅜ inch at the top, outside measurement; 6¾ inch at top and ⅞ inch wide, tapering down to ¼ inch at bottom, inside measurement. It will take a plate 9 × 6½ inch, and will hold fourteen ounces of syrup water for washing the plates in. It must be firmly *screwed* together with thirty-eight screws, at intervals of about 1½ inches apart.



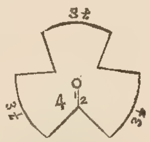
The two side pieces, A and B, are of mahogany ⅝ inch thick, by 1¼ inch wide, also the cross piece.

The thumb-screw is a fine thread swing-glass screw, sold at most ironmongers, and used in making frames for looking-glasses.

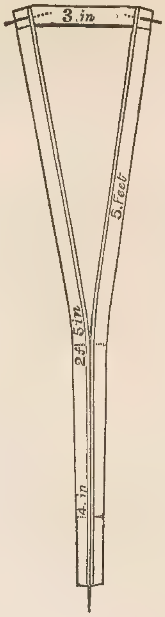
In making the bath, first screw one side on to the ends, well varnishing the wood several times, *and run the varnish between the joints when screwing up;* then screw on the other side, using plenty of varnish; let it set for a few hours in a warm room, then trim it up nicely and bevil off the top; screw on the mahogany side pieces A and B, let in the screw nut, and screw the side pieces firm; cover

the cross piece C with two ply of velvet, then with *thin sheet india-rubber* and strips of leather, and with brass pins nail it down. Varnish it over several times and the bath will be complete.

Of camera stands two will be wanted — the one with legs 4 feet 2 inches long, and the other 5 feet 2. The first serves for portraits and for the tent, the other for landscapes. The stands that are usually sold have heavy iron or brass tops, and birch or ash legs, and are generally constructed on a plan offering every impediment for packing, unpacking, and work. The following can be readily made, and are light, cheap, and convenient. The top is best made of mahogany, in form of a triangle — that is, a circular disk with three notches at regular intervals apart, thus :—



The "legs" of yellow pine, 5 feet long, $7\frac{1}{8} \times \frac{3}{4}$ inch wide, six brass ferules, six screws, and three steel pins, are all that are wanted.



After cutting out the top of the camera stand, cut six pieces of brass wire 2 inches long and about the thickness of a tobacco pipe; drive these into the mahogany top, each sloping a little downwards, thus :—

Then fit each of the six pieces intended for the legs with a brass ferule, and bore holes through them to fit the wires in the top; now sink in the three steel pins and screw them each with two screws; well varnish the legs, and when dry screw them firm with two large screws long enough to pass through both pieces forming the stand legs. The one large screw should be 4 inches from the bottom, and the other 2 feet 5 inches, thus a sufficient spring will be secured to clip the top of the stand. It will be, when finished, a good looking article, and quite as useful as it looks.

THE PATENT MIRROR STEREOSCOPE.

No one who has attended to the subject can have failed to realise the palpable fact, that a vast increase in the excellence and value of the stereographic illustrations published during the last year or two has been accomplished. At first, any thing that displayed the principle of the instrument used to view them was regarded with interest. The stereoscope became a household necessity: it was found to be universally popular; hence a demand arose for specimens, to enable the happy possessor of such a coveted treasure to display its accomplishments. In those days stereographs were secondary considerations: they acted simply as *food for the stereoscope;* but as the doctor in the play of "Le médecin malgré lui" remarked, with reference to the positions relatively of the heart and the liver, "nous avons changé tout cela."

The demand created was discovered to be an ever-craving appetite that grew upon that which fed it, and thus a requirement for a constant supply of better and still better productions set in. The demand, of course, was complied with, and eventually it occurred that the stereoscope and stereographs quite changed places. Purchasers ceased to buy the latter to show off the former, and began instead to procure stereoscopes, because they were *necessary,* in order to enjoy fully the beautiful illustrations that were every where offered to the public. It is also a fact worthy of note that the public were not slow to accept the offers. Under these circumstances attention was naturally turned towards an improvement of the instrument with which to view these miniature picture galleries; and many ingenious contrivances for its more effective operation, whether as regards increased comfort in using, or greater excellence in its illusive capabilities, were brought into play.

It was the case of literature over again: writers beget readers, who in their turn become thinkers; and thinkers give birth to writers — an ever-recurring cycle. So it is with stereoscopes and stereographs: as the excellence of the latter approaches nearer and nearer to perfection, the greater becomes the necessity for improved appliances wherewith to render them fully available for delight and instruction.

It is needless to pursue this theme further. We are not about to write a history of the stereoscope; but we could not forbear glancing at the events which have led up to the production of the very beautiful and effective instrument which we are about to describe, and which we regard as being about nearly perfect of its kind as it is possible for any one to require.

It will be remembered by many of our readers that, early in the current volume of The Photographic Journal, we described the achromatic stereoscope, introduced by Messrs. Smith, Beck, and Beck, the eminent microscope makers and opticians, of Coleman Street, London. The same firm is about to bring out a new form of stereoscope, under the title of our heading. We purpose, in a future number, giving an illustration of the instrument, but in the mean time consider it of sufficient interest to attempt a verbal description.

The original achromatic stereoscope, which may be regarded as a temporary fixture, if we may use such a phrase, was adapted rather for the purposes of displaying subjects at a *soirée,* where those present are generally in constant circulation, or for examining a series, by a single individual seated comfortably at his ease, with light conveniently adjusted, and all *en règle;* but in a family party or friendly gathering, the great charm of such an occupation consists in the possibility of passing the instrument, charged with its slide, from hand to hand.

The patent mirror stereoscope, like the other one, is furnished with achromatic lenses, and consists of a flat base of mahogany, or other ornamental wood, of about five inches by six. Above this, at an angle of about fifteen degrees, is a framework of wood, blackened, into which is set a plane silvered glass mirror; thus the compound base board is formed something like a wedge, being about one inch thick towards the eye end, and about half-an-inch towards the opposite edge. This arrangement allows of a certain small space *between* the mirror and the wooden part of the base, and in that space another piece of wood traverses, and is arranged so as to slide smoothly in and out by means of a rack and pinion, worked by a milled head on the right side of the instrument. To this sliding piece, at right angles, is fastened another piece, which carries the achromatic lenses fitted into brass tubes, also adjustable, and by means of that adjustment, together with that of the rack and pinion before described, a very extensive range of focus is insured, so as to render the instrument suitable to every kind of sight.

The arrangement for holding the slides consists of an elegant light framework of blackened metal, attached to the thin edge of the base, and of course at right angles to it; and this is strengthened by a metal strut, attached to the metal frame at one end, and to a piece of wood placed between the lenses at the other. This metal strut also subserves another purpose, viz. — that of keeping in place a division to shut out from each eye the possibility of its seeing also a portion of the picture belonging to its neighbour. This division is made of very finely-ground glass, and is most pleasing in its effect when viewing the specimens, which are supported in place by means of a couple of highly-tempered steel springs.

It will be perceived from the preceding description that there is no obstruction to the free admission of light from the top or either of the sides, and consequently this stereoscope may be used in almost any position of the light — that is, with the back or either side of the observer turned towards the source of illumination, for the division of ground glass previously adverted to does not perceptibly shut out any of the light, although it restricts the vision in the most perfect manner. This we regard as a very ingenious arrangement.

When the spectator *faces* the source of illumination, by slightly inclining the instrument downwards, the mirror comes into play and lights up the slide perfectly; and it appears to act in a way that quite removes the only objections to paper slides, that of rendering them strongly illuminated without showing the grain of the paper—an effect no doubt owing to the cross light destroying the shadows which in other cases render the inequalities visible.

The steel springs used to hold the slides in place are both mounted on a sort of minute metal bracket turning on a pivot — an arrangement intended to allow of their being turned aside so as to leave the metal frame entirely without projection of any kind. This is for the purpose of rendering the stereoscope available for examining *stereographs bound in books,* for which purpose it is adapted in the most complete manner; in fact, stereographs bound up with the letter-press as illustrations of the text can be examined *with as great comfort and ease* in every way by the Mirror

Stereoscope as ordinary slides are by the best of those now in use. This is no ordinary merit, and we have little doubt will act as an inducement to the publication of works illustrated by appropriate stereoscopic instead of ordinary prints. For works of travel or of scientific instruction, stereographic illustration would be invaluable.

A convenient *leather* handle is attached to the under part of the base board.

We have but one objection to make with reference to the instrument we have been endeavouring intelligibly to describe to our readers — it is mounted with semi lenses: we prefer them entire, for we hold that theoretically (and practically too) the use of a prismatic arrangement introduces errors that are needless; and though with achromatic prisms the only error of importance, lateral displacement of the image, can be rectified in mounting the pictures, the use of entire lenses would render special mounting in order to get the best effects quite unnecessary. This alteration may add somewhat to the cost of the instrument, but we should regard it as money well laid out. We shall certainly urge this point upon the manufacturers. At the same time, we do not hesitate to pronounce the Mirror Stereoscope unquestionably by far the most pleasant to use and most complete instrument of the kind that has been hitherto introduced.

NOTES OF A PHOTOGRAPHIC TOUR IN THE HOLY LAND.

No. IX.

MORE than two weeks have elapsed since I last wrote to you, and I am still lingering around Jerusalem. But I have not been idle, as my portfolio will show; for I have been beyond the Jordan for a week, and among the hills of Moab, on the east side of the Dead Sea, and photographed many interesting scenes.

"Parson," said John, "Parson, I can't stand this; let's be off, down to Nablous. I've had enough of this place; and so should you, I think."

"Nonsense, friend John; I have not half done. Besides, we must wait here a week for our letters that will be due."

"We can come back for them!"

The idea was not a bad one. It was dull enough, truly, and getting warm. A daily stroll over Mount Zion, and along the hill Acra, by the Church of the Sepulchre; an evening seat on the summit of the Mount of Olives, to watch the sun go down beyond the city; a profound sleep, with dreams of old glories all night — these were the daily variations of my photographic business, and for these I was willing to exchange a ride over the hills on the north of Jerusalem.

So we went.

Mounting at day-break, we emerged from the Damascus gate in the cold grey light of dawn, and crossed Mount Scopus as the sun was shedding splendour on the eastern walls of the city.

Our troop of Bedouins was in fine spirits. They had been begging us to move northward, and were not aware that this was but a ride and a return.

We slaked our thirst at the Well of Beeroth, if I mistake not the ancient name — a fine fountain on the south side of the hills which were once the site of Bethel.

The sun was high up when we passed the place of Jacob's sleep, and we paused not till late in the afternoon. The road was miserable nearly every inch of the way. The hardihood of our Arabian horses is incredible. One-fourth of this day's labour would have knocked up the best horses of any other breed. But we rode into the valley of Nablous almost as fresh as when we left Jerusalem, though it was a ten hours' ride.

Three times on the route we passed the spots where our friends had encamped. Can I speak adequately of the interest which such a spot possesses? A still valley—a place where the breezes seem to linger with delight — is made far more interesting by the fact that a little while ago it was the home of some pilgrim from far lands, whose tent was pitched here — who slept, and dreamed, and woke, and prayed here, and passed on, and left the valley for me to come into, and wonder who he was, and where and whither his pilgrimage.

We rode up the valley till we came to a spot where another valley crossed it from the west to the east. This latter is the Valley of Shechem. At the point of crossing it is one of the most interesting places in this holiest land of earth.

Its interest dates from remote time. It was here that Jacob digged a well, and here gave to Joseph a piece of land. The title to that little piece of land has changed hands often since then, and would be now somewhat difficult to trace; but passing over unknown and obscure owners, it is not to be doubted that this is the land of Joseph. Here, too, was his grave. The Moslems have a rude mud-and-stone structure enclosing one of their common grave mounds, which they point out as the tomb of the lord of Egypt. It stands out in the plain, and without doubt, is on the land of Joseph; and I know no reason to deny that it may with some fitness be considered near the locality of his grave.

A little way from it, on the side of Mount Gerizim, is the Well of Jacob, where Christ met the Samaritan woman. He was travelling up the valley from Jerusalem, and arrived at this spot, where He rested while His disciples went up the side valley to make purchases in the city, and awaited their return. The side valley is a ravine between Mount Gerizim on its south and Mount Ebal on its north — the mountains of blessing and cursing. Both are desolate and uninteresting. The valley is fruitful, and the grain on its fields looks well.

Turning sharply round the spur of Mount Gerizim we rode at an easy gallop toward the walls of Nablous, which is the modern representative of ancient Shechem. Rattling through the city, cursed by women and boys who scampered out of our furious way, we found the tents of our friends pitched on the usual travellers' camp-ground, just without the walls on the west side of the city. They were absent, so we took possession *sans ceremonie.*

Their servants obeyed our orders without hesitation, and in fifteen minutes we had a smoking dinner on the tent table, flanked by a bottle of claret, to which we were doing justice, when they returned from making a visit, and were greatly astonished to find their tent and dinner in possession of the Philistines.

But not displeased, if we may believe them.

What a delightful evening we had of it, all going down the valley together to the Well of Jacob! The moonlight was clear and fine for two or three hours, and the old mountains lifted their heads into a serene sky, as if they had something akin to it in their own antiquity and the grandeur of their story.

The scene was picturesque. We were all on horseback. Our Bedouins rode in two bodies — one before, the other behind us.

We seated ourselves at the well, and made the night musical with our discourse of the loved ones at home. But how often has this atmosphere been defiled since it vibrated with the voice of the Son of the Father, uttering the sublime mysteries of spiritual worship.

We slept, John and I, in the town, in a miserable hole, surrounded by half-a-dozen Greek Christians and some thousands of fleas. The night was, in brief, hideous. In the morning we went to see the synagogue of the Samaritans, of whom a miserable remnant yet worship God in the city of their fathers. A queer old man showed us an old book, which he said was in the autograph of a grandson of Aaron — though his voice was so cracked and his Arabic so poor (or so good) that perhaps we misunderstood it: it is probably he said — a grandson of Adam. An incredible antiquity is claimed for it, and *non credo.*

We breakfasted with our friends—stewed chickens, stewed mutton, a capital loaf of bread, an omelet, and coffee that was fit drink for Mahomet himself. Then we rode over to Samaria, a gay cavalcade.

The city of the Kings of Israel is almost gone. A few relics of its ancient splendour remain, especially long rows of columns, running half-way around the lofty bluff on which the city stood, and marking, perhaps, the line of one of its most splendid avenues. A ruined gateway at the western extremity of this row of columns, looking out to the distant sea where the ships of the world ride in the wind, and the mariners of nations lately born laugh at the faded splendour of the city of Omri.

No need that I should point out to you the passages of Holy Writ which we read on the hills of Samaria — prophecies that have had their literal fulfilment a thousand years. You know, or ought to know, them all.

The modern Samaritans are a fierce and furious race of men. They surrounded us with demands for money before we were fairly out of the city, and when we paid no attention they grew insolent. As we rode out of the place, a tall fellow attempted to seize the bridle of John's horse. John pressed the animal with his knee, and at a leap brought himself within reach of the scoundrel's skull. I heard a dull heavy blow, and saw him go reeling down. Then a cry rose that rang through the village. We put the ladies under Hassan's charge, and they plunged rapidly down the steep hill side, while we guarded the pass against the advancing villagers. We three were a host in such a case. We argued the matter a moment, until a stone came from the crowd

and struck John's horse somewhat heavily. He replied with a ball from his revolver, aimed at the man who threw it, but missed him. It was as well, for the crowd scattered in a twinkling, and left to us the field. As we descended to the plain a gun was fired from a loop-hole in the old church of John the Baptist, now a mosque. We sent three balls against the walls, and then Samaria was silent. D. T.

Meetings of Societies.

LONDON PHOTOGRAPHIC SOCIETY.

An ordinary Meeting of the above Society was held on Tuesday, the 1st instant.

The Lord Chief Baron Sir Frederick Pollock, President, in the Chair.

The minutes of the last meeting were read and confirmed.

The Viscountess Jocelyn, Frederick J. Smith, Esq., Capt. Rooke (Scots' Fusileer Guards), F. Joubert, Esq., Braham La Mert, Esq., Alfred Read, Esq., and C. Silvi, Esq., were duly elected members of the Society.

The Secretary read a letter, signed "One of the Collodion Photographers," from which we extract the following:—

"Pray, sir, stir up the profession to an act of bare justice! Enriched by Mr. Archer's invention, surely we shall feel a pleasure in sending his children into the world in a position equal to that which they might have attained had their father followed his original profession. Surely we are strong and numerous enough as a body, professional and amateur, to support three little children! £50 per annum for each child would probably be sufficient to provide them with a first-class education, so that £100 per annum would be wanted in addition to the Government £50. This amount could be raised at once, if 200 photographers would subscribe 10s. each per annum, or 100 photographers £1, 1s. each; but I should think there must be in Great Britain more than 200 well-to-do photographers, who owe their present gains mainly to the discovery of the late Mr. Archer.

"I have at present seven photographic businesses, each yielding a certain amount of income, and will therefore subscribe seven half-guineas or guineas per annum, during the next 10 or 15 years, if 200 or even 100 photographers will also subscribe a half-guinea or guinea per annum. For my own part, in rendering to the children so small a homage to their father's memory, seeing I cannot give them back their father, I should look on the money each year as a payment—a poor payment—a *very* bare act of justice.

P.S.—I forgot to say that I would propose not to touch the money now invested, but let it accumulate as capital to be divided among the children when they become of age."

The Secretary mentioned that the writer of the letter had communicated his name in confidence.

The Chairman stated that he regretted there was no paper to be read at this meeting, and announced that there were two or three gentlemen who had promised to make communications at the next meeting, one of whom was Mr. Ennel, and then asked if any member had any oral communication to make to the Society.

Mr. Roger Fenton said he saw many gentlemen present who no doubt had been working hard during the recess. Before they parted after the last meeting the question of lenses occupied much attention; and, to commence a discussion, he would state that he himself had been working wiih three of Ross's orthographic lenses, and comparing them with others of the old form by the same maker, he (Mr. Fenton) felt bound to confess that for landscapes he preferred the old combination. He had tried the orthographic lens for *portraits* and for *copying*, and in the latter application found that if the picture were not too large the lines were certainly very correct; but in forcing the lens to cover a surface beyond that which it was legitimately intended for, as is frequently necessary for landscape work, the distortion of the lines produced by the orthographic lens was more offensive than that by the meniscus form.

It also had the great defect that it would not give the foreground and distance with anything like a sharp definition. There should be a certain limit for distance, within which every object might be rendered comparatively distinct, and with the orthographic lens he could not get sufficient *depth of focus* to satisfy him as an artist. If by using a small stop any one had been able to produce satisfactory results, he (Mr. Fenton) would feel obliged by his communicating the result of his experience to the Society.

There had been a lens constructed by Mr. Sutton which had been said to produce great results; perhaps if any one were present who had been working with such a lens, he would favour the meeting by a statement of his opinion respecting it.

Mr. Bedford had employed the orthographic lens very little this summer, because when he had previously tried it he found that it possessed very few, if any, advantages over the old landscape combination. There might be some advantage in rendering architecture, and in other cases where there were flat surfaces, with less convergence of the vertical lines. For landscapes, in his opinion, the old form of lens was decidedly the best, both in depth of focus and in sharpness. The same result might be obtained by the orthographic lens; but in order to accomplish it the lens must be "stopped down" to such an extent as to make the increased time of exposure become of serious importance.

Mr. Shadbolt thought it advisable, in a discussion on lenses, first of all to determine what are the qualities required in a landcape lens? Then they would be in a condition to judge whether operators had conducted their examinations in such a manner as to allow of lenses of different construction being fairly compared the one with the other.

There were certain qualities in a landscape lens which might be regarded as absolutely essential:—fair correction of the spherical aberration to insure good definition was one; absence of all but a moderate amount of distortion was a second point. With regard to rendering foreground and distance both tolerably perfect it seemed to be forgotten, or not understood, that it is a question of *actual* and not of *angular* aperture—the reason being sufficiently evident; for with *any* construction of lens a large aperture in use is equivalent to taking a picture from *two or more points of view*, and superposing the results, thus introducing a painful amount of confusion, because objects in the foreground, if viewed from opposite side of a large aperture, would eclipse *different portions* of the distance. This was a fact that could be verified by any one, whether acquainted with optical science or not.

In delineating flat objects, or those situated nearly in one plane, the preceding observation did not apply, as *angular and not actual* aperture would be that subject to limitation. In near and distant objects delineated by a lens with an aperture of two-and-a-half inches, a confusion would ensue to the extent of the superposition of the picture seen by the right eye upon that by the left, or, in other words, equivalent to that of placing a pair of stereographs one upon the other.

He made these remarks because he perceived there existed a little confusion of ideas upon this point. To compare a lens of large size and long focus with one of small size and short focus required certain allowances and conditions of operation to be fairly adjusted.

With regard to the orthographic lens he thought there was one point which had been overlooked by Mr. Fenton in his statement. In noticing that the foreground was not well rendered by it, he did not state whether he had used a camera with a swinging back: certainly without it, when an orthographic lens was employed, to delineate a foreground with moderate distinctness as well as distance ought not to have been expected. One of the principal uses of the orthographic lens was, that with regard to architectural subjects, the photographer could rarely get to a sufficient distance from the object to include the whole properly on his plate. It was very curious that the defect of that lens could, in such cases, be actually turned to account. It was well known that parallel vertical lines, copied with an orthographic lens, curved with their extremities diverging from each other. In taking a square tower with a camera looking upwards, furnished with an ordinary lens, a cone would be produced; but as an orthographic lens, if placed horizontally, would cause the upper part to appear wider than the centre, so by directing it somewhat upwards (a great convenience when space is contracted) the lines would then become again nearly parallel.

There was also one advantage which he did not recollect to have been hitherto noticed—that by removing the back combination of an orthographic lens and reversing the position of the remainder, an ordinary landscape lens was produced of much shorter focus; so that by procuring an orthographic lens, two lenses were in effect obtained, one of which could be applied to a small camera, which was sometimes a convenience when away from home.

The Secretary stated that he had received a letter from M. Joubert, who had that evening been elected a member, and who had invented a new mode of printing which he termed "Phototype." M. Joubert stated in his letter that he had obtained a result which he would show if Dr. Diamond would pay him a visit. He (the Secretary) had seen the result, but M. Joubert did not describe the mode of production. The inventor also says he will present to each of the subscribers of the *Journal of the Photographic Society* a specimen proof, to which end he will at his own expense supply

the Society with three thousand prints in time for distribution with the ensuing number of the Journal. Copies from original engravings or from the life can be produced in large numbers, quickly, and at a very cheap rate — in fact a very large number were able to be taken off in a few hours.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The Annual Meeting of this Society was held on the 2nd instant, at the House of the Literary and Philosophical Society, 36, George Street, when Mr. Sidebotham presided.

Mr. Mann, the Honorary Secretary, read the Annual Report of the Society, of which the following is a copy:—

ANNUAL REPORT.

The Council of the Manchester Photographic Society, in presenting the Annual Report for the past year, have great pleasure in congratulating the members upon the satisfactory state of the funds, the Treasurer's Accounts showing a surplus of £29, 14s. 3d.

The number of members during the past year has not been so great, but it is hoped that there will be a considerable increase this session.

During the past year the meetings have been well attended, and the attention of the members has been principally occupied by general and very interesting discussions, upon the merits of the various processes and other discoveries in photography; and numerous apparatus have been exhibited to the members, comprising the latest inventions and improvements. Mr. Dorrington read a very interesting paper on printing glass transparencies, the results of numerous experiments made by himself and Mr. T. H. Nevill.

The Report of the Committee appointed to experiment on the various keeping processes was laid before the Society early last session, deciding in favour of the Taupenot or collodio-albumen process, as being the best process discovered for landscape photography.

At one of the meetings, Mr. Dancer brought an improved lantern with achromatic lenses, and the requisite apparatus for exhibiting transparencies, a great number of which (the production of the members of the Society), were shown upon the screen, making a very interesting exhibition, and enabling the members to judge of the kind of transparencies best suited for the lantern.

Mr. Sidebotham made some remarks on micro-photographs, claiming for our member, Mr. Dancer, the originating of these beautiful productions, and brought forward letters and specimens proving beyond a doubt that such was the case.

A large number of very excellent photographs have been presented by the members to the Society's portfolio during the past session, the same forming now a valuable collection, and constituting a very interesting record of the progress made by our Society in the photographic art.

Perhaps the most curious discovery made during the last year was that by our member, Mr. Young, that plates prepared and exposed can have the soluble iodide removed, and then be developed by daylight. Mr. Young's experiments have been repeated and verified by several of our members and also by members of the French and other photographic societies, and several theories put forth on the subject; but we are not aware that any practical use has been made of this curious fact: it would be well if some of our members would take this matter up, and carefully experiment upon it, so as to make it somewhat more than a mere photographic curiosity.

The year that has passed is not remarkable for any great discovery in photography; but rather for the effort made to perfect the processes already known. The dry processes, as they are generally called, have been much attended to and improved upon, and the ground cleared from many of the so called new ones; and from the letters in the journals and other sources, it appears that the decision of the public is in accordance with the report of our committee appointed to examine the subject, viz., that the collodio-albumen is in every respect the best dry process. One matter of considerable importance has been made public during the year, by an anonymous correspondent of the *Journal of the Photographic Society*, Number 82, page 258, and subsequently verified by Mr. Hannaford and other members of the North London Photographic Association, viz.—that plates prepared with nitrate of silver, and then dipped in a solution of chloride, so as to reduce all the pure silver to a chloride, are still in a high degree sensitive to light: this rather interferes with some of our previous notions, and opens quite a new field of experiment. Some of our members have been experimenting in this direction with different degrees of success: the results will no doubt be laid before our Society during this session.

The paper printing process is at last, thanks to Mr. Hardwich and Mr. Maxwell Lyte, now on a proper basis. The alkaline toning baths appear to satisfy all requirements; and although time alone can be the true test, there is every reason to believe that prints carefully prepared and toned by these processes are permanent, and it is to be hoped that photographers generally will at once discard the old toning baths. Carbon printing appears to be almost forgotten: some prints produced by our members were better than any we have seen by the originator of the process; but the difficulty, uncertainty, and unsatisfactory nature of the results, in comparison with silver prints, has caused the process to be laid aside.

Several specimens of photography applied to engraving and lithography have been published in the journals during the year: they are curious in a scientific point of view; but if as we suppose, they are to be taken as good specimens of the process, they are yet far from equalling engraving by hand for book illustration, or photographic prints for the portfolio.

Our report would be incomplete were we to omit to refer to The Photographic Journal, the special organ of our Society, and to thank our worthy Editor, Mr. Shadbolt, for the interest he takes in calling attention to any matters of importance brought before our meetings.

The Honorary Secretary then read the Treasurer's accounts, when it was unanimously resolved that the report and accounts be approved of and adopted by the meeting.

The President called the attention of the members to the subject of the election of the Council for the present session. He said there was no definite rule as to the way in which the election should be conducted, and thought it would be as well for the members to come to some resolution as to the manner of conducting the future elections He was himself in favour of a general ballot; but as they were not prepared that evening with any lists of the members of the Society, the Council had prepared a list of the names of the Council they recommended for the present year. If any member wished he could offer objections to any or the whole of the names if he thought proper, and move any amendment to the same.

After being proposed and seconded, the list was unanimously agreed upon by the meeting.

The following are the names of the Council elected for this session:—

President.

The Lord Bishop of Manchester.

Vice-Presidents.

Joseph Sidebotham, Esq.
J. B. Dancer, Esq., F.R.A.S.
James P. Joule, Esq., LL.D., F.R.S.
Arthur Neild, Esq.
H. E. Roscoe, Esq., B.A.
W. C. Williamson, Esq., F.R.S.

Council.

The President,
The Vice-Presidents,

Mr. J. Compton, Jun.	Mr. T. H. Nevill,
„ Samuel Cottam,	„ A. Patterson,
„ J. Dale,	„ John Parry,
„ J. Dorrington,	„ J. J. Pyne,
„ G. Higgins,	„ F. Töbler,
„ G. T. Lund,	„ H. Young,
„ T. Mabley,	„ S. W. Williamson,
„ James Mudd,	„ G. Wardley.

Treasurer.

Mr. Edwyn Offer.

Honorary Secretary.

Mr. Edward Mann.

The thanks of the meeting were then voted to the officers for their services during the past year.

A resolution was then agreed to by the meeting that the annual meeting be always for the future held on the first Wednesday in October. It was then moved and carried that four of the Council who have attended the least number of council meetings retire annually from the Council, and that they be rendered ineligible for re-election during the next year.

After a general discussion as to how the Council should be elected on future occasions, a resolution was passed as follows:—"That a list containing the names of the members of the Society should be supplied to each of the members, and that each member mark the names of those he wishes to be on the Council."

The President then made a suggestion that, as the funds of the Society were in a very satisfactory state, he thought it might be desirable to reduce the amount of the subscription to half-a-guinea and half-a-guinea entrance fee, when, after some discussion, it was formally resolved upon and carried.

One of Mr. Sutton's new symmetrical triplet lenses, was exhibited by Mr. Pyne, which the President explained, and stated the manner in which he had tested its capabilities, and that he was considerably disappointed with it — much light being lost, a very small field given, and no very sharp focal point.

Mr. Dancer made some comments upon experiments he had made with Ross's orthographic lenses, and said he had found the lenses gave very different results by varying the distances between the lenses; he also thought a lens should not be judged of by

simply examining the picture on the grey glass, but that a photograph should be taken in order to form a correct opinion.

Mr. MABLEY said he thought dry plates were not so accurate as wet collodion for testing the quickness of a lens, as a picture under-exposed might often be fully developed by a dry process.

Mr. DANCER agreed with Mr. Mabley, for he had noticed that pictures taken on dry plates in a stereoscopic camera with twin lenses and different apertures often showed a very slight difference when developed.

The PRESIDENT then explained several instances where dry plates had been accidentaly exposed for a very few seconds, and yet traces of the picture were found mixed up with the after-exposed picture.

Mr. WARDLEY stated several similar cases which had occurred to him.

After a vote of thanks to the President the proceedings closed.

CHORLTON PHOTOGRAPHIC ASSOCIATION.

THE monthly meeting of the above Association was held on Wednesday evening, the 9th instant; Mr. ROGERSON in the chair.

After reading the minutes of the last meeting, which were confirmed,

Mr. JOHN HEYWOOD read a paper *On Toning Positive Prints.* [See page 282.]

A very interesting discussion followed. The meeting considered the No. 2 solution the most approved.

Mr. WARDLEY said they all knew the result of the old toning bath, and he should like to know how these prints were affected by lapse of time. He was of opinion they would remain as they were.

Mr. LLOYD then exhibited a very neat apparatus for copying a picture by gaslight. It consisted of a quarter-plate camera, elongated, to which a lens and a tin cone were fitted to the mounting, over which was a semicircle of gas tubing, perforated. This was fed by a flexible tube from a common gas-burner. The apparatus would copy a picture in from eight to twelve minutes. It was thought the best contrivance yet exhibited, as the light was uniform, and could be used by day or night.

Mr. WARDLEY exhibited a frame for printing transparent stereographs from an uncut negative, invented by Mr. Compton.

Mr. HOOPER exhibited an amusing toy for photographers' use, to froth albumen and please the children: when the frother was turned a dancing figure expanded. This caused much amusement.

A vote of thanks to the chairman concluded the meeting.

Practical Instructions on Coloring Photographs.

By ALFRED H. WALL.

CHAPTER VI.

WATER COLOURS.

Preliminary Observations.

ALTHOUGH we are now fairly afloat in our practical studies, you will not, as I have before said, derive much benefit from my instructions if they are merely confined to material colours, their uses and modes of application. In its place I have already spoken of the relative value of colours, of their effects in combination, their characteristic peculiarities, &c. (see the chapters on colour and pigments). I must now say a few words upon the proper perception of colour in nature.

It is so common in observing the various objects about us to take for granted certain general ideas as to their respective colours that a more thoughtful habit of perceiving is one of the first and most important qualities to be acquired by the student. As he learns to see artistically, and catch

> Those tend'rer tints that shun the careless eye,

he will experience no surprise at the raw, crude, unnatural appearance presented by his early efforts, nor any longer feel at a loss to account for such failures.

The education of the eye *must* accompany that of the hand, or all my efforts are vain, and all the time you may spend in reducing these instructions to practice will be so much of man's most precious gift wasted.

The best means of acquiring what is familiarly known as "an eye for colour," is by the careful and thoughtful observations of every object around you, and the study of such paintings * as are celebrated for their colouring — not the first without the last, nor the last without the first, but *both* — not slightly, briefly, and at long intervals, but deeply, lingeringly, and frequently. You must be thoroughly in earnest or you will fall into that mechanical drudgery, something better perhaps than house painting, but infinitely less respectable, and far, very far below anything artistic. There is no medium.

There are unfortunately those who *will* preach that old-fashioned, pernicious doctrine that "artists are born and not made" — whose mischevious appeals to egotism, idleness, and ignorance, find with the many too ready a hearing. Some hug it to them because it flatters their vanity — *they* are "the chosen of the earth;" others because it is a salve to their consciences for procrastination — "Oh! I can do it in no time, when I like; there's no hurry." Others, again, because it is an excuse for failures, due only to a want of energy and perseverance. To refer to a quotation already given in my maxims:—"There is a degree of impiety in pleading a want of faculties, when the real want is proper industry and method to make right use of them." Labour is the only price of excellence in every department of our knowledge, and if you are prepared to pay this price, and come to your work with a bold heart and patient love, I will guarantee you a measure of success fairly proportionate to your efforts. It would be easy to illustrate my opinion on this subject by reference to the lives of eminent painters, but it would lengthen my digression too seriously. Believe me, I do not speak ignorantly, but like that amiable young-old gentleman in "Bleak House," from "the deep wells of my experience." Without being controversial or disputative, I desire to deal honestly with you (as a guarantee of this intention I appended my name to these papers), and this should not be, did I fail to warn you against this pretty piece of fanciful theorising which age and popularity has rendered so mischevious, as this theory of providential partiality certainly is. A predisposition for the study of art may have its origin in peculiar circumstances connected with early life; but with average intellect, manly courage, and a more than ordinary share of perseverance, I can see no reason in nature why victory should not crown the "good fight."

To return. If you possess a photographic camera, examine the image of any object or person in sunshine upon the ground glass, and mark well the wondrous brilliancy of the mysteriously-blended tints and colours; or the countless variety of shades and tints which go to make up that which the uneducated eye recognises, in a misty indefinite idea, as "flesh colour." *Such images are capital studies.*

When you examine paintings, optical images, or the realities of nature, bring to the task the principles of art, which have been discovered or supported by the great artists of past ages, and *test their value for* yourself — *humbly* yet *boldly*, for there is no real energy, no true perseverance, without *conviction. The traveller who is conscious that he knows the right road travels quickly; but the wayfarer in an unknown path goes with slow, hesitating steps, and is often brought to the extreme verge of the gulf — despair.*

In studying from pictures, beware of indiscriminate imitation, and never copy the style or system of any one master until you have carefully matured your own judgment on his productions.

That you may not, with many, think it an unconquerable disadvantage to colour upon the photograph, I must remind you that most of the great old masters, and many of our best modern painters, completed their pictures in monochrome before they coloured them. This fact has been vouched for by very high authorities. * My friend, Mr. H. Keens — himself a most excellent colourist — in a little MS. work upon this subject, says: — "Titian frequently commenced his pictures by painting them entirely with black and white, thus satisfying his eye with the *chiaroscuro* of his work previous to applying colour. Photography now furnishes the artist with images possessing the most beautiful gradations of light and shade, quite equal to the black and white paintings of that prince of painters; and, if he can bend his proud scorn of the humble camera to accept its valuable aid, he has now fair scope for emulating that great master, and may advance modern art to an equality with the best productions of his predecessors."

I am afraid that Titians are not very easily "made" by any process, but I do believe that artists who can devote their whole energies solely to colour, will by-and-bye greatly surpass those the greater part of whose life and nearly the whole of whose best energies are swallowed up in the study of correct drawing, in light

* See maxim No. 12.

* Sir J. Reynolds, Merimee, Field, Mr. T. Sheldrake, and many others. The fact is also supported by the discovery of unfinished pictures and the examination of damaged ones by Van Eyck, Perugino, Leonardo da Vinci, Fra Bartolemeo, Guido, Rubens, Raphael, Titian, and others.

and shade; for so deep and subtle a subject is that of colour that it is not easy to devote to it too much time.

With these few preliminary remarks by way of advice and encouragement we will enter upon our lessons in water colours.

The method of execution adopted in water colours varies with almost every artist who uses them, I shall more particularly recommend that species of manipulation with which I am most familiar.

The first thing to be done is to select

MATERIALS.

Brushes for water colours are prepared in hog's-hair, camel's-hair, and sable, in quills and in tin ferules: some are long and tapering, others short and thick, some flat, others round. The hog's-hair brushes are of service in the use of body colours to lay broad, flat tints, the camel's-hair for large washes of colour; and the sable for the finer work, for which also select the best French sables. Sable pencils are dark brown and light red in colour—the former are the softer and the latter the stronger kind. With the exception of such pencils as are necessarily very small, for the putting in of minute markings and outlines, choose as large a brush as you can conveniently work with, as by so doing you obtain a full, broad touch, infinitely superior to the "scratchy effect" caused by the use of those too small and fine. When purchasing pencils, ascertain in the first place that the hairs are of a proportionate length, then dip their ends in water, work them to a point on your thumb-nail and ascertain if it forks or divides, and see whether, after pressure, it springs back to its original form; if thus tested, and it neither forks nor fails in its elasticity, it is a good and valuable servant and must be retained. A flat camel's-hair brush or two should be procured for washing and sizing. Be careful not to leave them in the water, and rinse them from colour before putting them aside. A stiffish brush, somewhat worn at the point, is best for "hatching."

The author of the preceding paper has, in order to render his communications of greater practical value, kindly undertaken to criticise the work of, and give advice to, students in colouring, through the medium of these pages, for which purpose specimens may be sent, with a stamped and directed envelope *for their return, to* A. H. Wall, Esq., 11, The Terrace, Walworth.

Miss D. (Kingsland)—The background I recommended in a previous number must be painted with more turpentine than oil, in order that it may dry with but little gloss. In a carefully manipulated negative its effect for transparency and softness cannot be excelled. Do not place it too near your sitter.

Alabastrino—As your question does not bear directly upon my province, I ought, doubtless, to hand over your epistle to the editor for its reply; however, I will break a rule to say, that such productions have the certainty of destruction in their very elements. If preserved carefully, and excluded from light, they may—and do—last some time; but even then you will find them vary in appearance with the state of the atmosphere. I am proud to own acquaintanceship with Mr. G. W. Simpson, but never heard him claim the invention of these pictures—nor do I think this gentleman has ever publicly stated that they would be found, "under all circumstances," perfectly permanent.

John Blunt—It is a good print for colouring, but it is spoilt beyond the hope of recovery for water colours, by an abominable "French background"—one of the most inartistic and tasteless of photographic blunders. What would you say of an artist who cut out the figures from his water-colour sketches to stick them upon a piece of stained paper? The *painter* who did this would be laughed to scorn—and why should not the *photographer?* By another proceeding he produces results *exactly similar:* he cuts out his "dummy," and lays it over his printed figure to protect it, while the hitherto protected background, in its turn, is exposed to light; and thus *two hard edges are brought into contact,* leaving a *black* or a *white* outline of more or less distinctness (according to the operator's skill—but always horribly distinct), quite round the figure, causing that which would otherwise appear the gently retiring boundary of vision to seem like the sharp palpable edge given by scissors, which, in fact, it is. I did hope such childish inventions had vanished before the increasing spread of correct taste and good sense. Another reason against these backgrounds will be found in the fact, that flat smooth surfaces *advance* instead of retiring, as all behind the principal figure should of course do. Care and cleanliness will always command at least a passably clean background; and if in the print you find white spots, a fine brush, with a little colour, will enable you to "touch them out." Should the spots prove black, touch them out in the negative with opaque colour, that they may be white in the printed positive. I can only advise you to get another print, for however streaky or spotty its genuine background may be, you will find less trouble in painting these defects out than in destroying the harsh black or white line round the image.

A School of Design-Student—Photographic colouring is, *in competent hands,* very remunerative. At present too many inferior colourists are engaged by photographers; but I believe the fact originates in the dearth of really artistic colourists. I can therefore honestly advise you to persevere.

M. Mansion—When refering to the use of dry colours, I asserted that I had never seen them applied with good effect to paper. I can scarcely regret having done so, as the fact promises to renew an acquaintance I had the pleasure of making some years since with the above-named veteran colourist. M. Mansion has shown me some exquisitely beautiful specimens of dry colouring on paper. My own practice on paper has been chiefly with water and oil, and the few experiments I once made on the same with dry colours did not encourage me to proceed, I therefore as fairly stated my convictions in the words above referred to, as I now do a fact on the other side.

J. P.—Although you may wish to study in water colours alone, I would not advise you to neglect the chapters already given. I cannot just now remember in which number they commenced. Begin with large heads, and remember Pope's words—

"———— Failing is no shame,
And cowardice alone is loss of fame."

A Drawing-Master—For dry colours size the print first, and varnish just as you would upon collodion. The pumice-stone powder gives a tooth to the surface.

Letters to a Young Photographer.

No. XXIII.

My dear Eusebius,

Let us return to business, and talk of processes, and methods, manipulations, and formulæ, as best suits your taste and curiosity. The man who can invent a new process superior to any we possess deserves the reward the monarch promised to him who could invent a new pleasure. What we appear most to want is a really infallible mechanical process; such as will suit those who are deficient in aptness, manipulatory skill, taste, judgment, and every other intellectual quality. We want something "adapted to the meanest capacity," like shuffling a pack of cards, or winding up a clock. I know a certain self-dubbed professor who could invent such a process if he were to set about it; but *he won't try!* Therefore the awkward squad of would-be photographers must bide their time, till the professor, moved by their sufferings, falls into the melting mood.

Let us talk of paper—waxed-paper, if you will, as that appears to possess great attractions in your eyes. You know that when paper is oiled or varnished it becomes much more transparent than before: to what this result is owing I shall not now attempt to explain, as the cause is much too recondite for your tender understanding. Well, then, oiled-paper is much too troublesome to operate with in aqueous solutions, obviously from their mutual repellent qualities: waxed-paper is much less so, therefore we employ wax to embue our paper with, and render it translucent, and tougher, or parchment-like. If the paper be selected of suitable quality, you may obtain negatives on waxed-paper which will yield positives as good, and some think even better, of many classes of subjects than those obtained from glass negatives. They are *softer*, that is, there is less sharpness, which in architectural subjects is a great advantage. The only objection to the waxed-paper process is, that it is slower than collodion or albumen; still, for architectural subjects it has become, in consequence of improved manipulation, quite quick enough for all reasonable purposes.

The principles of photography on waxed-paper are the same as those of collodion or albumen; the paper is substituted for glass, and the sensitising agents are applied direct to the surface of the medium instead of being mixed with a vehicle like albumen and collodion. The object is to obtain on the surface of the paper an even layer of iodide of silver, upon which the image is received and impressed, and afterwards developed by suitable agents. The methods of obtaining this layer of iodide are very numerous, but good results may be arrived at by those I shall now proceed to describe.

One advantage possessed by waxed-paper is, that it may be preserved in a sensitised condition for a considerable space of time; because the wax preserves the organic matter from the action of the salts of silver. The idea of employing this material is due to M. Le Gray (to whom we were very nearly being indebted for the collodion process), and it gave an immense impulse to photography; it was only eclipsed by the introduction of collodion. Many photographers continue to prefer the waxed-paper process, notwithstanding the advantages possessed by albumen and collodion.

The selection of the paper for this process demands the greatest care and attention. I have found Marion's papers the best, and as they are so readily obtained waxed, I think you had better avoid waxing the paper yourself, as it is a very difficult and troublesome operation to perform.

In un-waxed paper the nitrate of silver comes into immediate contact with the organic fibres of the paper, and decomposition ensues. In waxed-paper, on the contrary, the nitrate and iodide of silver are not in immediate contact with the fibre of the paper, which is protected by the wax, hence it remains much longer unaltered when sensitised; and it is probable that if we could impregnate paper with some substance that would render it as impermeable as glass, it is possible we might obtain a sensitive surface which would retain its sensitiveness unchanged for an indefinite length of time. We arrive very nearly at this result by M. Gaumé's method of impregnating paper with a solution of gutta percha.

You cut your waxed-paper a little larger on one of its sides than the frame of the camera slide, and iodise it in the following manner: — Take

Clarified serum of milk	11 ounces.
Iodide of potassium	2 drachms.
Bromide of potassium	30 grains.
Sugar of milk	$2\frac{1}{2}$ drachms.

This bath will not keep long, especially in warm weather, as the serum enters into a state of fermentation. When used it must be filtered into a dish, and the paper floated upon it, and by means of a glass triangle remove all the air bubbles that may form. It will be difficult to moisten the waxed-paper at first, but by keeping it immersed the iodide of potassium gradually overcomes the resistance of the wax, and the iodide covers the paper uniformly. Without the addition of the sugar of milk the difficulty of imbuing the paper with the iodide would be still greater.

The waxed-paper must be left in the bath from half-an-hour to two hours, or until the paper is thoroughly penetrated with the solution; it may then be suspended in a warm room by one angle to dry, attaching a piece of bibulous paper to the lower corner to facilitate draining.

The waxed-paper upon being taken out of the bath will be found quite altered in appearance; its transparency will have dissappeared, and its colour is frequently changed by the action of a small quantity of free iodide. The change in appearance is due to the action of the iodide upon the wax; it appears to have become porous or spongy. But it is only the physical condition of the wax that is altered; upon warming the paper before the fire the paper resumes its primitive aspect.

Exposed to the light the paper assumes a violet hue, which, however, is of no importance, as it disappears when the paper is passed into the sensitising bath. The sheets must however be kept in a close portfolio, out of the influence of air and light, else the iodide will become decomposed. The paper will, if properly protected, keep in good condition for an indefinite length of time.

The paper is sensitised when required for use, by floating on a bath of aceto-nitrate of silver, composed as follows: —

Distilled water	1 pint.
Nitrate of silver, pure,	$1\frac{1}{4}$ ounce.
Glacial acetic acid	1 ounce.

Have ready, side by side, three perfectly clean porcelain dishes which have been employed for no other purpose. Into the first pour a sufficient quantity of the aceto-nitrate of silver, filtered, if necessary, and nearly fill the others with distilled water. Have also a quantity of coloured bibulous paper, cut into squares a little larger than the sheets of prepared paper. Then carefully immerse each sheet of waxed-paper in the sensitising solution, and by means of a glass triangle remove all the bubbles of air as they form. However much discoloured the paper speedily becomes white in this bath, and in one or two minutes the reaction is complete. Then take a pair of horn pincers in each hand and lift the sheet of paper by the two opposite corners; let it drain, then put it into one of the dishes of distilled water, move it about gently, and then pass it into the next dish of water to rinse it. Lift it out and let it drip for a few moments; then place it on a folded sheet of bibulous paper, cover it with another, and absorb all the superfluous moisture. Then put it on a fresh sheet of bibulous paper, cover it with another, and place upon the latter the next sheet of sensitised paper, alternating with bibulous paper, so as to make a pile: this done, place a piece of wood larger than the paper on the top of the pile, put a weight upon it and leave the whole until dry; the sensitive paper will come out perfectly flat, and not curl, unless it be placed in a very warm place.

If you prepare more than six or eight sheets at a time, the water in the dishes must be renewed, and the blotting-paper dried, or a fresh supply obtained. This sensitising operation must be performed in the dark room by artificial light. The proofs obtained from the paper first sensitised in this bath will exhibit very pure whites and blacks; but they will be less sensitive and perhaps less harmonious than those subsequently prepared, which is as much as to say that an old bath is better than a new one. The effect may be obtained by dissolving one ounce and-a-quarter of nitrate of silver in three ounces of distilled water, and adding to it, drop by drop, a small quantity of the iodide of potassium-bath, stirring meanwhile; a yellow precipitate forms, which is iodide of silver; then add the remaining seventeen ounces of water and the acetic acid; filter, and preserve it in the dark; it is then ready for use. The paper should not be allowed to remain in the nitrate of silver bath more than one or two minutes at most, just long enough to convert the iodide of potassium into iodide of silver, otherwise the nitrate of silver is apt to extend its action to the paper itself, and decompose it, notwithstanding the repeated washings we may submit it to: the sensitised paper rapidly darkens and even blackens entirely in the gallic acid. If the paper is removed from the sensitising bath at the proper moment it will keep in good condition for several days, and better endure a prolonged development. But it is preferable to expose the sensitised paper in the camera as soon as possible after it is sensitised.

Photographic Glossary.

Varnish—A substance which, being spread over any surface, covers it with a sort of glassy coating, impervious to air and moisture, against which agencies it is the object of the varnish to protect the body to which it is applied. It also imparts gloss, and heightens the colour, and as in the case of wood, developes all the beautiful details of the grain, &c. The substances used as varnishes are very numerous: they are white of egg, wax, gum-arabic, and numerous resins dissolved in various menstrua. Varnishes proper consist of certain resins dissolved in fixed oil, as linseed; in essential oil, as turpentine; and in alcohol, forming respectively oil varnishes, turpentine varnishes, and spirit varnishes.

In the alcohol and turpentine varnishes the menstruum entirely evaporates, leaving the resin in its original condition. In the oil varnishes, on the contrary, the menstruum does not evaporate, but becomes oxidised in the atmosphere, and resinous, entering into intimate mixture with the resin dissolved in it, and greatly modifying it.

In photography we are chiefly concerned with the spirit varnishes, and in forming them our chief attention must be given to the resin; for obviously, in varnishes of this class, the quality must entirely depend on the nature of the resin. If the resin be brittle and pulverulent before it is dissolved it will retain those qualities after the alcohol has evaporated. Again, if the resin be unctuous and soft, it will produce a sticky varnish, and dry but very slowly. By a judicious mixture of various resins, whose opposite qualities modify each other, a varnish free from objectionable properties may be obtained.

Varnishes—Spirit—Most of the resins are more or less soluble in alcohol, in proportions depending upon the strength of the spirit. A specific gravity of 0.825 is of very convenient strength. The most important resins are animé, benzoin, dammar (or soft copal), elemi, mastic, and lac (bleached or white lac). Upon examination in their natural state, these resins exhibit very different properties. Some are covered with a whitish dust or powder, showing that they are easily pulverised, as the powder arises from the abrasion of the pieces against each other: such are sandarach and dammar. Varnishes made of these resins alone are very easily scratched, and will bear but little abrasion. Mastic is more tenacious — it softens in the mouth, becoming plastic, while the others are brittle between the teeth. Elemi and animé are more tenacious than benzoin. Lac is hard, tenacious, non-pulverulent, and not easily abraded or scratched; but it is apt to scale off the glass to which it is applied: it therefore requires to be mixed with dammar and elemi resins, to supply deficient qualities.

The formulæ for varnishes may be infinitely varied, according to the qualities of the resin taken as the basis. It may

require the addition of a pulverulent, or brittle, or unctuous resin to correct its defects. The addition of these must respectively depend upon the object and judgment of the varnish maker. As a general rule, alcohol sp. gr. 0.825 will dissolve about one-third of its weight of a resin, but dammar dissolves as much as seventy-five per cent. The resins are not always completely soluble in alcohol: a mucilaginous or gummy portion frequently remains in suspension, and the soluble portion must be filtered out. The addition of spirit of rosemary to the alcohol increases its solvent power. Chloroform produces a similar result.

Foreign Correspondence.

Paris, November 10, 1859.

The 18th of July next promises to be a very interesting epoch for celestial photographers. The total eclipse of the sun on that day will not, unfortunately, be visible in this latitude, the nearest favourable point of observation will be Spain, from Bilboa, Santander, and Oriedo to Tortosa, Oropesa, and Valencia, where there will doubtless be a great gathering of European astronomers from England, France, Italy, Germany, and Russia, besides those of Spain. Astronomers are already busily engaged in calculations, and it is noted that at the time of the eclipse the four principal planets, Venus, Mercury, Jupiter, and Saturn, will be visible in the neighbourhood of the sun, forming a sort of rhomboid; a combination so rare, that many centuries will elapse before it can occur again. Not until 1887, twenty-seven years hence, will there be another eclipse of the sun visible in Europe at all comparable with that of July next. The photographer will require lenses of 50 feet focus, and the chief point to which his efforts will be directed are the obtaining a series of proofs of the luminary between the first and last contact. M. Faye has made some valuable suggestions on the points of observation that demand most attention, and of the means of obtaining them. His suggestions to the photographer are, that at a minute previous to total obscurity, the camera being properly directed towards the sun, that in place of a sensitised plate a band of sensitised paper be unrolled at the rate of about three quarters of an inch per second. So long as the sun's rays are visible the paper will be darkened; but at the moment of the disappearance of the last ray of light—of that sudden transition from day to night characteristic of total eclipses—the photographic impression will suddenly cease. During the darkness several yards of the paper unrolled will, of course, be lost; but the re-appearance of the first solar ray will register itself by its photographic action. The apparatus must be furnished with a counter, in order to measure the time that elapses, which must also be registered on the sensitised paper: this may be done by means of a pendulum, which can be made to intercept the rays of light from second to second. The exact progressive variation in the light can thus be accurately estimated.

At present the photographs of the sun, moon, and planets, are, notwithstanding their importance, only portraits. Those obtained by M. Quinet have established the following results:—

1. We can determine the hour, photographically, with the meridian telescope, without the aid of an observer, with a precision at present unattainable in any observatory.

2. On the proofs obtained with a lens of long focus we can measure the smallest spots in the sun, and their variations, and thereby give an unlooked-for extension to the physical constitution and rotation of that planet.

3. We can observe an eclipse photographically, by which we gain an advantage over every attempt hitherto made to measure the size or the orientation of the horn, the depth of the phase, &c.

In registering contacts photography will eventually supersede the observer, and suppress, with him, all the sources of error so mysteriously allied to the physiological condition of our senses.

The interest attached to the forthcoming eclipse cannot be overrated, and it is hoped, that by a combination of resources, ample justice will be done to the rare occasion. From atmospheric causes the total eclipse of the sun which took place last year was, photographically, a disappointment. It is to be hoped that the season and the climate of Spain will be more favourable to the efforts of photographers.

I must commend to your attention M. Asser's improved method of carbon printing, which, if it prove at all successful, will solve that problem in a most satisfactory manner. It is the true desideratum, and we cannot but hope it realises what the inventor leads us to expect. J. P.

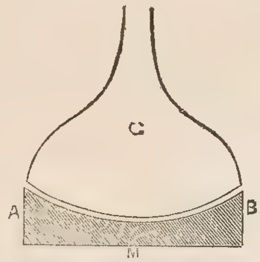
Correspondence.

☞ We are at all times willing to assist our Correspondents to the utmost of our ability, but we can only do so through the medium of the Journal. We cannot give private replies except to personal friends.

ENLARGING FROM NEGATIVES.

To the Editor.

Sir,—I perceive, from your diagram, that I had not understood you in your former paper. Regarding the parabolic mirror, I took it for granted that the mirror you mentioned was to be placed with its axis at an angle of 45°. Now, in your diagram, which is quite explicit, the acting part of the mirror is a portion of the parabaloid on one side of its vertex; then, allowing it to be so, the upright outline B would be parabolic, while its transverse section would be circular.



Whether the figure be a sphere or parabaloid, it will reflect parallel rays to an imperfect focus; but as it is wanted only to illuminate the negative with *converging* rays so as to diverge after refraction by the lens, then the slight confusion at its focus is unimportant; and certainly on this point you are perfectly correct. Also, as regards printing, I find by experience that *direct* sunlight does not produce nearly such a fine picture as can be obtained by a good argand burner and powerful condensers; but the fault may be my own.

I am also of the same opinion as yourself that a spherical mirror would answer nearly as well as a parabaloid for the purpose of illuminating the negative.

Your proposed method of cutting the mirrors out of glass globes is quite practical and cheap. If, however, parabolic mirrors are wanted, there are several ways they can be made: first, when the glass globe is hot, to hang it up to elongate; secondly, a parabolic mould could be made, and the glass blown into it while hot.

I would suggest a parabolic mould, A B, of a square outline, proportional in size to the dimension of the mirror wanted, and of a parabolic concavity coinciding with that part of your parabolic diagram P X P in your Journal, page 254. Into this mould the hot glass could be blown, and a supply of cheap and accurate concave parabolic glass mirrors silvered as you describe.

You very justly observe it will be unquestionably advantageous, as in the first place we are quite free from chromatic error (however little it be); secondly, we are free from the great loss of light by reflection at four surfaces, and also from the imperfections, bulk, and weight, of the glass condensers; and thirdly, and not least, notwithstanding the superiority of the mirror, they can be supplied at a price within the reach of all. I am, Sir, yours, &c.

Newcastle, October 24th, 1859. THOMAS DAVIDSON.

A GROWL AT THE LAST MEETING OF THE PHOTOGRAPHIC SOCIETY.

To the Editor.

Sir,—I cannot resist the desire to vent a little good-humoured indignation at the character of the meeting of the Photographic Society last evening. On hearing the minutes read I was struck by the fact of the date—June. Now from June to November is five months, and during all this time not a single paper appears to have been prepared for the benefit of the members, though the room was full of gentlemen from all quarters! even the Chief Baron was there to grace the first meeting of the Society; and what was done? Six or seven members were balloted for, and then the announcement was made that there would be a paper read at the next meeting! and so the Society separated.

As to the attempt to get up a discussion about lenses, it signally failed. Now what does all this come to, but that the Council does not consist of *men of business?* What was the Secretary about? Surely if some of the members of Council or he had only spoken, there are many who love the art who would have been but too happy to have done something for the amusement and instruction of their fellow-members; instead of which, what a lame and impotent conclusion! I heard of one gentleman who had come some considerable distance, and had ordered his carriage about ten o'clock; but the meeting was over before nine.

I believe I express the feelings of most of the members, that these meetings are looked forward to with *great pleasure and expectation;* how great then must their annoyance to find meetings carried on like the last! nothing on the table, nothing even to raise a discussion upon—a bare board of green cloth! I should think that the instrument makers would have been glad to have paid, if necessary, for the privilege of exhibiting their newest devices and instruments. A few pictures taken by any new process, or stereoscopic views taken during the summer, would have been gladly sent if asked for. Either would have afforded something to look

at instead of the new ballot-box, which makes still more noise than the old one. Surely the ballot might be managed better: we want to hear something about PHOTOGRAPHY, not have our time taken up with listening to the sound produced by dropping the balls into the ballot-box, which constituted almost the entire amusement of the last evening.

Surely a sub-committee might be constituted for the sole purpose of arranging a pleasant meeting—by writing to members for papers, writing or speaking to instrument makers for specimens of apparatus and chemicals. If the Council cannot furnish such a sub-committee, let them get a few of the members to form one. In other societies one generally finds plenty to amuse and discuss. Look at the meetings at the Royal Institution, how the tables are covered!—look at any other public society, and then mark the contrast.

I really do not know where the blame lies, but if these things go on members will leave and get up another Society; in fact the last meeting was not respectful to the members. Why not mention in the last number of the Society's Journal that no paper would be forthcoming? I myself had been very ill and not quite recovered; but I braved the chance of a relapse to hear something about my favourite, delightful study, and great was my disappointment not to say indignation.

There was a great deal of annoyance expressed last session respecting the paucity of subjects. I hoped that during this one a more active spirit would prevail; but from the experience of the first meeting, what can one anticipate?—I am, yours, &c. AN OLD MEMBER.

November 2nd, 1859.

[We must admit that the meeting was anything but a lively one. No doubt our correspondent is under the impression that by sending us this letter he is giving us a sly rub, probably supposing that we are, as formerly, a member of the Council, which is not the case; but had we been on the Council, we should have published his very reasonable letter all the same.

The fact is, such men of business as are on the Council—and there are some good ones too—are outnumbered. In short, as we have before repeatedly observed, the Council consists of a ludicrously unwieldy number, which, in our opinion, should be reduced to *one-half*, or better still, *one-third* of its existing complement. If this were done, *each* member of it would feel himself personally responsible for the good management of affairs, and all would work with greater willingness.

In any revision of the laws which may take place this point deserves the first attention.

We do not at all agree with the policy of attempting to get up another Society; there is nothing amiss with the Society by our correspondent's own showing. The true remedy is to be found where indicated on a former occasion by our worthy President, whose words we quote: "If your Council acts in a way that you do not approve, remove it and appoint another."

Our own opinion is that most of the present members of Council would be efficient enough provided their number was sufficiently reduced. Should members generally agree in this opinion, there is plenty of time to give notice of such proposition before the next annual meeting.

In making these remarks—which we should however not have done but for our correspondent's letter—we have solely the welfare of the Society at heart: we have nothing to gain, but much to lose, by its injury.—ED.]

EUSEBIUS IN SEARCH OF A MASTER.

To the EDITOR.

SIR,—I am, as you are reminded every fortnight, a young—I might say a very young—photographer, learning my art from a letter-writer whose epistles appear fortnightly in your pages. Now, sir, "be judge yourself" whether or not I am to be pitied. Just as I had acquired an intense desire to proceed with fresh instructions—just as having found my "nerves strong" and my "head cool" enough to—coat a plate! and "take" my grandmother "*in*" the shadow of "the jasmine arbour," with her *tea-service* "BEFORE HER," and the favourite cat on the *opposite* seat (by-the-bye, the result wasn't satisfactory somehow — grandma looking grimly black, and barely visible in the shadow beyond the beautifully prominent tea-service, and Fido not to be found in the black patch under the table); just—to resume—as I had got one of the "best pictures I ever saw," and one which my teacher, "seriously speaking," pronounced so good as to draw from his generous heart the classical gift of a "penny meerschaum" and "four ounces of the best 'cnaster;" in short, just as I was getting on famously—my master ceased to teach photography, and took to the drawing and painting business, after insinuating that I had got another sense than the usual five, which, as he evidently didn't mean common sense, must of course be nonsense. Now, sir, I am naturally amiable; but, really—well, never mind. All I've to say is, Eusebius is in want of a photographic teacher, unless his old master will resume his instructions.

By-the-bye, may I also inquire if, as according to my teacher, only great painters are artists, what the little ones are? and if only great generals have a right to be called soldiers? or if only such men as Stephenson and Brunel are to be called engineers?

If the writer of the *Letters to a Young Photographer* should resume the instruction so abruptly deserted, will you, dear Mr. Editor, call his attention to the following quotation from one of his former epistles:—"I have before me *a very excellent* treatise on photography, which exhibits a *singular talent for digression* * * * *. He (the author in question) introduces the bath, and then some thirty pages are occupied about silver, nitric acid, &c. Presently he introduces the camera, and then some thirty pages are occupied with a treatise upon light. He *speaks of colours, and lo! a lengthy disquisition ensues upon a new theory of colour.* Proceeding in this *digressive* style, it is with the utmost difficulty that the reader can contrive to dovetail the various pieces of instruction." Without comment, I am, dear Mr. Editor, yours, &c. EUSEBIUS.

[Your master says, "he thought you wished to become a *Photographic Artist;* but, since it appears that you only want, as our American cousins phrase it, to *make* pictures, your obstinacy be on your head"—so he "returns to business."—ED.]

ANSWERS TO CORRESPONDENTS.

J. C. M.—We have noticed the abuse you mention.

JOHN CHINAMAN.—We believe the article you mention is "made to sell."

B. SONGE.—Consult the "Photographic Glossary," under the appropriate head.

R. GUNTER.—The specimen sent is well adapted for colouring, both in tone and intensity.

A. BRISBANE, Greenwich.—We have not seen any photographs of the late aurora borealis.

W. H. D.—The best is always the cheapest, if a *fair* price be charged. Most dealers supply priced catalogues.

J. BACHE.—Asphaltum is only another name for bitumen, but there is a factitious asphaltum obtained from coal.

W. CARTER, Lincoln.—Nitrate of uranium is not nearly so dear as nitrate of silver. You have been grossly overcharged.

ARCHIBALD BURNS, Edinburgh.—Several correspondents are desirous of knowing where copies of your stereographs can be purchased.

FOCUS.—It is very probable that the ground glass is mounted in the frame on the wrong side; the roughened surface should be nearest the lens.

FRED.—You cannot expect to understand those matters without a knowledge of the rudiments of chemistry. Six months' diligent study will make you *au fait.*

SAM SLICK.—We cannot say what gum juno is; perhaps it is gum juniper, the berries of which contain ten per cent. of a resin possessing an odour of turpentine.

S. H.—A bad workman always throws the blame on his tools; with bad photographers it is always the "nitrate" or the "hypo," or anything but want of tact and judgment.

H. DOUGLAS, Edinburgh.—The only chance of stopping the evil is to immerse the paper for a few minutes in a quart of rain water, acidulated with a few drops of hydrochloric acid.

ARGENTUM.—Your bath is doubtless in an alkaline state. Immerse a fresh piece of reddened litmus paper, and see if it becomes blue: if it does, add a homœopathic dose of nitric acid.

C. SMITH.—We have before noticed the garbled extract from our report on Derogy's lenses. We did *not* say that they are "equal to six ordinary lenses." Please to refer to the original report.

COSMOS.—You cannot expect to do much good until March next; meanwhile study the back numbers of this Journal, and make notes for reference on those points of which you are ignorant.

VERNIS.—The highest strength of alcohol allowed by the Excise has a specific gravity of 0.825. You can make your spirits stronger by adding dry carbonate of potash or pearl ash, which is insoluble in alcohol.

JOB.—Your patience is exemplary. Write again to the fellow: if that elicit no notice you can recover the amount of the bill in the County Court, after you have returned him his rubbish with due notice of your intentions.

T. RILEY, Jun.—We have so many inquiries about stereoscopic cameras that we shall probably prepare an article on the subject shortly; in the meantime you must be content by our again saying a bi-lens camera by all means.

C. L. * * * *—The stereographs sent for review have arrived, but are such that we cannot commend; the subjects being without exception puerile or vulgar (one or two have both objections). The only favourable point about them is, that they are certainly very well printed. Under these circumstances we must decline any special notice, and would prefer returning them to you if you will oblige us with your correct *address.*

H. BARTON, Croydon.—The method suggested by M. Gaume consists in making a solution of gutta percha in benzoin; when clear, decant it. Paper immersed in this solution becomes waterproof, and if used for printing positives upon, the hypo does not penetrate the paper, but acts only on its surface, and, consequently, is easily removed with mere washing. The paper becomes slightly translucent, and has quite a glassy appearance. If it presents a granulated appearance, holding it before the fire will render it even.

RECEIVED.—T. Mills, R. S., J. T. T. &c. W. Q. in our next.

☞ *All* EDITORIAL *Communications*, BOOKS FOR REVIEW, *&c., should be forwarded to the Editor*, GEORGE SHADBOLT, 2, *Upper Hornsey Rise, London, N.*

All ADVERTISEMENTS *and* LETTERS *on the* BUSINESS *of this* Journal, *should be addressed to the* PUBLISHER, 32, *Castle Street, Liverpool.*

THE PHOTOGRAPHIC JOURNAL.

No. 107, Vol. VI.—DECEMBER 1, 1859.

We published in our last Mr. Ennel's rejoinder, in accepting our challenge (thrown out in No. 99, page 184, of the current volume) to discuss the principles of the swing-back camera, upon the utility of which contrivance we hold diametrically opposite opinions. Our opponent inquires—"is not *error* synonymous with *wrong in principle*." We reply certainly not. The *principle* upon which achromatic lenses are constructed is perfectly sound, viz., that of employing a medium of high dispersive and low refractive properties to correct the errors of another medium of low dispersive but highly refracting qualities; yet no lens is absolutely achromatic, however nearly it may approach to that condition—not from *error of principle*, but from unavoidable imperfection of materials and workmanship; hence we assert that even the best lens is only one in which the *errors* are reduced to a minimum.

It will be apparent, from Mr. Ennel's definition of the words *point* and *distortion* as applied in his communication to the *Journal of the Photographic Society*, that our demand for it was absolutely necessary, in order to avoid involving ourselves in "a question of words and names;" and why that gentleman should with such ultra latitude consider the former to signify "visible forms with certain proportions," while at the same time he narrows the signification of the latter word so strictly as to mean "representation in which the relative proportions *differ* from those of the original," without any limitation, would seem somewhat inconsistent, unless we are to suppose that he does it with a view to supplying us with a stumbling-block or two to embarrass the freedom of our movements. We have to thank him for supplying a reason why we assert that in the case of a small distant window (only) to be delineated the swing-back camera would be *misapplied;* but unfortunately he has not assumed the correct one. It would be misapplied, because useless: the small distant window at right angles to the line of vision would not be *perceptibly* distorted even if the back of the camera were inclined; but it must be borne in mind that we are not obliged to incline it upon *all* occasions, whether rightly or wrongly.

We object to the major premiss, that "*all circles* projected on an inclined plane are ellipses;" for, if the circle be itself inclined to the axis of vision (the precise case in which we advocate the use of a swing-back), its projection would not be the transverse section of a *cylinder*.

Our antagonist's definition of *distortion* is too narrow when applied to the matter under discussion, for the reason that, if taken in the strict sense to which he has confined it, viz., any (even the smallest) departure from relative proportions, then every camera picture delineated upon a plane surface must of necessity be more or less distorted over its whole surface, except that part *immediately in the axis of the lens;* for it is obvious that as we approach towards the margin of the picture the plane of delineation becomes more and more oblique to the axes of the pencils of rays depicting those parts, and consequently, according to Mr. Ennel's views, more and more distorted. We admit, nay we have asserted, that in a *strict* sense this is the case, because the subjects at the margin of every camera picture, a plane of delineation being employed, must of necessity be taken upon a *slightly larger scale* than those in the centre of the plate; and therefore, in using a plate inclined to the axis of the lens (as is sometimes done in a swing-back camera), we *decrease* the error on one side of the axis as much as we increase it on the opposite side. We were therefore justified in the assertion, that if, when employing a plane surface of delineation, we incline it to the axis of the lens in certain cases, the error, if regarded even in its most limited sense, is only one of degree.

The truth is, that in applying the word *distortion* to a photograph, *perceptible distortion* is what is intended to be understood; and if any of our readers will take the trouble to focus a camera upon a small distant window, and swing the back to the utmost extent usually provided for, they will find that no *perceptible* distortion will occur. Having then cut away the foundation of our friend's ingenious argument to prove that we have assented to his proposition, we need scarcely attack the superstructure, seeing that it falls of itself.

Mr. Ennel speaks of a circle being projected on to a plane as represented by the transverse section of a *cylinder;* but when a lens is employed this is not at all the case, the lines all crossing in the axis, so that even if there were no deviation of the rays the figure described would be that of two cones with their apices connected.

However, in point of fact, each mathematical *point* of a subject is delineated by means of a pencil of rays radiating therefrom being collected together in the conjugate focus of the lens, and the figure described by each bundle of rays is that of two cones with their bases united, the bases being sometimes at right angles, but oftener oblique to the axis. It will be therefore readily understood that instead of any such simple figure as that of a cylinder playing any part in the matter, a figure of a very complicated character is that really described by the rays of light in their passage through the lens. If, then, as we have shown, that distortion in its strict sense must occur in every case where a flat plate is used, whether it be inclined to the axis of the lens or not, and that by inclining it in certain cases we merely dispose of the error somewhat differently, *without increasing its total extent*, it is surely better in submitting to the scarcely perceptible variation of scale, which we must do in using a plane surface, to have all parts in tolerably distinct focus, than to have them all out of focus and indistinct; hence we reiterate our assertion that, theoretically and practically, the swing-back is a highly useful adjunct to the camera in certain cases, viz., where the objects to be delineated lie in a plane oblique to its axis.

We have carefully endeavoured to avoid any expression that might by possibility give offence to our opponent; but as we find that even the most harmless ones are occasionally misconstrued or misapprehended, we cannot conclude without stating that we have had no intention of writing anything that should be regarded as offensive.

At the last meeting of the Photographic Society an attempt was made to get up a discussion relative to the merits of the various kinds of landscape lenses—with but little success. Is it not possible that the failure may have arisen in consequence of fear of what the speakers might find attributed to them when

repeated in the Society's Journal? We speak feelingly upon the point, for we have been quite horrified to find what a tissue of *nonsense* has been set down to our account in the *Journal of the Photographic Society*, in consequence of the few words we uttered upon the occasion in question. We beg any of our readers who may have read the report of the meeting in the organ of the Society to peruse the statement of what we really did say, which they will find in our last. It will be an act of charity to us, for we quite wince under the imputation of such absurdity. We shall certainly protest against it at the next meeting.

PHOTOGRAPHIC CONTRIBUTIONS TO ART.

In the various branches of natural-history science, systems of classification have been repeatedly proposed, adopted, modified, and discarded in favour of others which have been found necessary to be framed in order to meet the ever-increasing requirements arising from more extended knowledge of species; but in spite of the most carefully guarded definitions, it is found that in nature there do not exist the arbitrary lines of demarcation which the systematist is obliged to adopt for his own convenience—the gradations from one marked form to another, at first sight totally different, being so imperceptible that every now and then, as intermediate ones become presented to our notice, we feel perplexed to decide under which particular head to classify them. We find ourself in this predicament at the present moment, having received from Mr. George W. Wilson, of Aberdeen, some exquisite stereographs, several of which are so truly "PHOTOGRAPHIC CONTRIBUTIONS TO ART," that we find it necessary to remove them from our usual "NOTICES OF RECENTLY PUBLISHED STEREOGRAPHS," upon the principle that though every peer is of necessity a man, every man is not a peer. In making this distinction with regard to one series of half-a-dozen of those before us, and two or three others, we do not thereby intend to depreciate in any way the remainder, nor to assert that they are in the smallest degree deficient in artistic excellence; but we have here for the first time recorded by photography some of those marvellous effects produced by the *setting sun* that act so powerfully upon the feelings of the spectator, producing that sensation of calm enjoyment and repose which long dwells upon the mind as "a green spot in memory's waste."

It may be thought by some of our matter-of-fact friends that we are somewhat unusually enthusiastic in our admiration of that same *setting sun*. Be that as it may, we do thoroughly and heartily enjoy the effects of the ever-changing hues of the masses of clouds tinted and glorified by "the greater light that rules the day," but more especially during the last half-hour of its presence above the horizon. Our favourite sitting-room has an aspect looking due west, and we never voluntarily omit an opportunity of drawing our chair to the window in order to gaze our fill at the gorgeous scenes to be witnessed as the sun sinks slowly behind the hill in front of us. No wonder, then, that we feel somewhat more than usually impressed with the charming specimens before us; for though it is true that the colours are absent, yet we have a faithful transcript in black and white, not of the letter but of the spirit.

Most of our readers will doubtless have seen, and if so, will certainly remember, the beautiful illustration of clouds and sea with a brig in the distance, the work of M. Le Gray, which was published between two and three years ago. The productions which we are now criticising belong somewhat to the same class, yet there is a difference, and in our judgment a very marked advance. While M. Le Gray's picture was admitted by all to be most beautiful, it gave the idea of *moonlight* albeit taken at high noonday; but here we have sunshine—glorious, liquid, golden sunshine!—that gladdens the heart while it soothes the spirit. Again, M. Le Gray's masterpiece consists of clouds and sea alone, exquisite in their way, but destitute of shadow, or nearly so.

It has generally been regarded as perfectly futile to attempt to take a photograph of any subject whatever with the sun looking directly into the camera. As a rule the proposition holds good, because all objects so seen—*except those in a horizontal position*, as for instance water—must appear in deep shadow, and consequently without detail; but, like other rules, this one is not without an exception, as Mr. Wilson has proved in his six sunset views of the Loch of Park, in Aberdeenshire, the *locale* of which is the same in each.

On the further side of the lake, the waters of which are here and there stirred by a gentle ripple, is seen a range of hills. Here and there low banks clothed with bullrushes peep above the waters, while in each one of the series fantastic clouds, more or less adorned with golden linings, which form a sort of trimming to the most favoured ones, surround or partially obscure the god of day, whose beams, descending in a golden shower, kiss the light ripple of the waters, and mark out a track of gorgeous brilliancy. In each one, also, is seen a boat, but varied in position and differently tenanted. That which we call the first of the series must have been taken late in the afternoon, and in each succeeding one the sun is seen lower and lower, till in the last he has just disappeared.

We cannot venture to say with what fraction of a second of exposure the negatives were taken: suffice it that they are sharp and brilliant. It is not a little difficult to decide upon which to admire most where all are so charming; but, for brilliancy of effect upon the dancing ripple, that one where the sun appears nearly free of clouds is perhaps the most sparkling; while for calm repose we should select that in which the boat is tenanted by two young females, and a child seated on the point of land to the right of the picture.

There is also a remarkable effect produced in one where the strip of light forms a background to the boatman who is rowing.

There are three other specimens which we consider should be included under our present heading as presenting something new and valuable to art, viz., The Gathering Mist, Muchals, No. 74; The Lower Falls, Moness, Aberfeldy; and The Second Falls, of the same locality.

It is only those who have loitered in the hill country who will be familiar with the peculiar way in which the mist gathers about and clings to the sloping sides of the lofty hills, while all else around is bright and clear. 'Tis then that the hills appear "clothed as with a garment," and Mr. Wilson has caught the effect most perfectly, the mist being purely local and semi-transparent, like the gossamer muslin half veiling the limbs of a young girl.

The other two subjects which we have above indicated are in character allied to that we have just noticed, in the beautiful rendering of that impalpable atmosphere of moisture which will be instantly recognised by those who have been fortunate enough to visit the scenes made charming by the ever-flowing streams bounding from rock to rock, while those who have not will now be able to realise perfectly the idea of what such scenes are like. The water, too, in these specimens does not appear as a mere patch of white, but just as in nature—foaming, *woolly*, semi-transparent, with the spray literally pounded up to a fine powder. Add to all this the picturesque detail of rocks, shrubs, ferns, &c., grouped in charming disorder, and one may well conceive what a rich treat is in store for those who are wise enough to avail themselves of the opportunity of procuring such unsatiating pleasure. To artists these productions will prove invaluable, enabling them to examine and study at their leisure scenes that they can only rarely visit, and such scenes that only faithfully to imitate in these their poetical aspects is to create an undying reputation.

Here we must pause for the present. We have more yet to bring under the notice of our readers connected with Mr. Wilson's productions, but we must defer further mention of them till our next; for, as we endeavour to play the part of a

true and faithful witness, it is not without careful examination and study that we can be in a condition to do justice either to our readers or to the artist, and all this occupies time and demands calm consideration.

EXPERIMENTS WITH ARSENITE OF SODA.

By R. L. Maddox, M.D.

At this season of the year we may expect out-door photography to descend to its minimum, therefore anything suggestive to increase the value of the low actinic power will doubtless find its proper estimation among those who purpose taking their stand against wind and weather.

In the letter from Mr. Church (Journal of August 15th) the statement that arsenite of soda had been used in the collodion used in the instantaneous pictures produced by Mr. Kibble, led me to hope that I might find it of value in the paraffine process. On trial it did not give me any advantage —I thought rather the reverse; but this might have depended on the mode of using or quantity employed.

As an albumenised solution was prepared with arsenite of soda I determined on trying it in the preparation of dry plates, Fothergill's plan. The collodion used to first coat the plates was a mixture of several kinds, which collectively contained iodide and bromide of potassium, iodide and bromide of ammonium, iodide and bromide of silver: it was of a sherry colour.

The plates were sensitised as usual; after washing, to get rid of the free nitrate, some of the following solution was poured over them: —

Arsenite of soda .... 16 grains.
Rain water.. 3 ounces.
The white of one egg. These were mixed a fortnight previously.

To one ounce of the above an ounce of rain water was added, and filtered through sponge for use: the plates were drained, washed, reared up to dry; the drying being completed by artificial heat.

To some of the weak albumen and arsenite of soda liquid an equal part of saturated solution (in the cold) of gallic acid with one drachm of Beaufoy's acetic acid to each ounce was added, and then poured over the sensitised plates, which were washed, &c., and dried.

A plate prepared by each method was exposed at the same time in a bi-lens camera (the day clear, but very windy, sun shining moderately) for 20 seconds. The time that I should have allowed for a dry plate according to my usual plan of preparing would have been at least 60 seconds.

The development was proceeded with gradually, using equal parts of the above indicated gallic acid solution and a one-grain pyrogallic solution, with a couple of drops of a 20-grain solution nitrate of silver.

The pictures showed very slowly. After the parts were pretty distinct the strength of the developer was increased: here its colour altered sensibly, but did not become at all muddy. Gradually the plate with the arsenite albumen liquor showed signs of fogging, or indistinctness, very general over all parts of the plate *equally*, whilst the one with the addition of the gallic acid solution remained clear and bright. As the developer became coloured it was changed to fresh, and finally only pyrogallic was poured over it. The plates when cleared showed a marked difference, the vegetation being much more out in one than in the other.

The use of gallic acid was, I believe, suggested by Major Russell. So that you see I have offered nothing new beyond the combined use of arsenite of soda and gallic acid. As to the keeping qualities of the plates I can say nothing, but the accompanying prints from the negative with the gallic acid will speak for themselves. I am quite confident from sundry experiments that the plan now stated gave me a great *increase in sensibility*.

I have also used the arsenite of soda for positive printing paper, with varied solutions of nitrate of silver, both as regards strength and composition, also with gelatine and albumen. Some I found sufficiently sensitive to be impressed in a short time in the camera and developed by gallic acid. The hyposulphite appears to destroy the colour of the darkened parts much less than in the chloride papers. On some I poured boiling water, which produced only a slight change in colour when dry.

However I do not consider the experiments sufficiently decisive for more than a cursory allusion. Different papers are to hand for trials; but the weather and other engagements have put a stop to their continuance.

I send this in the hope some of your readers may gather something useful from the preceding remarks.

Woolston, 24th Nov., 1859.

N.B.—I do not know how the Poison Bill may affect the sale of arsenite of soda, if useful.

THE DIFFICULTIES OF THE DRY PROCESS.

By W. Ackland.

[Read at the Meeting of the South London Photographic Society, November 17, 1859.]

I purpose this evening to attempt a description of some of the difficulties of the dry processes, and trust the discussion which follows may elicit some explanation of certain defects which sometimes occur, and yet scarcely admit of a lucid explanation.

Before commencing, I would remark that it is my intention to confine my observations principally to the collodio-albumen and Fothergill process, as these are more frequently employed by the amateur and professional photographer than any others.

The difficulties encountered in the dry processes are:—

Blistering,	Fogging,
Opaque lines in the excited collodion film,	Want of intensity,
Brain-like markings,	Insensitiveness,
Reticulations,	Stripping off of the film,
Water markings,	Pin holes in the high lights.

Blistering.—This defect seldom occurs in working Fothergill's process, but is often observed in the collodio-albumen, gelatine, and oxymel process, &c.; indeed amateurs often assert that if blistering could be obviated the collodio-albumen would be the most certain of any known process. Many have attempted to explain the cause of this defect—one writer ascribing it to dirty plates, another to employing a collodion containing too much ether, and a third too much alcohol, whilst a fourth ascribes all the annoyance to using the iodised albumen too thick. Now I propose to attempt no explanation, but to suggest certain precautions. These are:—

Never coat a plate in a damp room.

Slightly warm the glass plate before pouring on the collodion.

Let the collodion set until the drop at the lowest corner drained from will receive the impression of the finger before lowering the plate into the bath.

Prepare the iodised albumen from eggs about a week old in preference to those "new laid."

And to dry the plate most thoroughly after the albumen solution is applied, and take especial care to prevent it becoming again damp before the final exciting.

The collodion many be deemed the great cause of blistering, and to this we must turn our attention. This must possess fluidity, yield a creamy film, and be adherent to the glass plate. To ensure fluidity it should be iodised a month before used, and if, when that time has elapsed, it still possesses glutinous properties and yields blistering plates, we must produce the proper state of fluidity by the use of an alkali added to it. The best plan to effect this is to add to each pint of the iodised collodion about half-an-ounce of recently and highly dried carbonate of soda, and to shake frequently during two hours, then let it rest for another two hours, and pour off the upper clear portion into a perfectly dry bottle for use. To ensure a good creamy film the collodion must be iodised with a mixture of iodide of cadmium and iodide of potassium, and should contain at least six grains of the mixed salts to each ounce.

The adherence to the plate is somewhat dependent on the temperature at which the pyroxyline is prepared, for although very high temperatures have been recommended, it is found desirable in practice not to exceed 150° Fah. in preparing this substance for the dry process. The collodion mentioned above being highly iodised requires an exciting bath containing not less than thirty-five or forty grains of nitrate of silver to each ounce, and should be very slightly acidified with acetic acid.

Opaque lines in the excited film is the next defect. These lines occur in the direction of the dip of the plate, and may be traced to one or more of three causes: —

1st. To the plate being immersed in the bath before the film has been allowed to set sufficiently.

2nd. To the exciting bath being weak: and,

3rd. To the accumulation of alcohol and ether in the bath.

This latter cause is one of very frequent occurence, and is certain to give rise to such lines, more especially if the bath solution is not of full strength.

The remedy is to neutralise any free acid that may be present by carbonate of soda, and then to boil in a porcelain capsule for half-

an-hour, so as to expel the volatile portion, and, when cold, to filter, slightly acidify, and dilute if necessary.

To ascertain if dilution is necessary, a bath-tester should be employed. This is simply a glass tube about ten inches long and half-an-inch in diameter, with a scale of divisions, commencing with 0 near the bottom, and extending to 100 near the top. To use it we must proceed as follows — [The bath-tester was produced and handed round] : —

Take of highly dried and perfectly pure chloride of sodium 84½ grains, and dissolve it in twenty ounces of distilled water; this forms the test solution, and requires to be made *with exactness*, or the result obtained by its use will be erroneous. A second solution is also needed; this is made by dissolving twenty grains of bichromate of potash in one ounce of water.

To test the strength of a bath solution, take the bath-tester and drop into it one drop only of bichromate of potash solution, then fill the tube up to the lowest division, marked 0, with the bath solution, and add the standard test solution, gradually shaking at frequent intervals: when the colour of the precipitate, which was at first brick red, changes to a lighter tint, add the test solution more gradually, and continue to shake up between each addition. Continue to add the test solution, drop by drop, until the red tint of the precipitate suddenly changes to white, showing that all the nitrate of silver is decomposed, and that enough test solution has been added. Now read off the division on the level with the surface of the fluid in the bath-tester, and it will be equal to the number of grains of nitrate silver contained in each ounce of the bath solution. Thus, supposing, after having performed the experiment, the fluid in the bath-tester stood level with the 39th division (counting from below upwards, the same as the tube is figured), this would indicate that each ounce of the bath solution tested contained thirty-nine grains of nitrate of silver.

This plan of using bichromate of potash, to show by change of colour when all the nitrate of silver is converted into chloride, was published some years since, and, although but little used, answers perfectly in all cases except to test the nitrate of silver bath, after having been used to excite collodio-albumen plates. In this case, the precipitate which forms on adding the test solution remains coloured, however much is added; therefore, the use of the bichromate of potash solution must here be dispensed with and the test solution added, gradually shaking after each addition, and allowing the white chloride of silver which is found to settle down, until the test solution ceases to produce any more cloudiness in the clear portion of the contents. The division level with the surface of the fluid in the bath tester here also indicates the number of grains of chloride of silver per ounce.

Reticulations, or crape-like markings in the film, arise from a defective sample of collodion being employed; or it may be caused by using a small quantity of collodion to coat a number of plates, as, in hot weather, the evaporation of the ether leaves the collodion in a condition to give these markings, but may be prevented, in this case, by adding a few drops of ether, from time to time, to supply the loss by evaporation. A collodion prone to these reticulations may often be made to give an uniform film by adding to each ounce eight or ten drops of chloroform.

Marblings, or brain-like markings, in the high lights of a negative often occur, and may be traced to a defect in the collodion, careless development, or partial washing after exciting.

Collodion yielding a compact film is very liable to possess this defect, and should be at once discarded for one of a more porous nature; indeed, I may here remark that a compact film is totally unfit for use in any dry process, and is the cause of many of our failures. Carelessness in imperfectly mixing the pyrogallic and nitrate developing solutions is often a source of these markings, as is also unequal washing after removal of the excited film from the nitrate bath, and the remedy is here, of course, apparent.

Water Markings.—These have been described by a writer in one of the photographic journals as occurring chiefly in the skies, but occasionally in other parts of the picture, and are of all shapes and forms: sometimes (on a minute scale) very like what are called in silks, and other fabrics, "water markings," and, at others, patches of varying length and breadth, either ending abruptly or shading off gradually into the upper edge of the film.

These markings were a constant source of annoyance to me in my earlier attempts at Fothergill's process; but, at last, I succeeded in discovering the cause, viz., using a collodion yielding too compact a film. By constantly using Powell's collodion, of late I have not seen a single marking; and in order to prepare a specimen of this defect to submit to your notice, it became absolutely necessary for me to prepare a collodion on purpose, and, as you see, my success has been very great, — for the plate now handed round is one of the worst cases of this kind of marking that can possibly occur.

The remedy is here, as in the last case, to use a porous film; for however carefully you may wash your plate, whether in four drachms, one ounce, or four ounces, on applying the albumen to a plate coated with a compact film, these defects will at once form, and, on the plate becoming dry, be very apparent.

Fogging occurs in the "dry process" in a somewhat similar manner to the same appearance in the "wet," and may arise from the state of the bath, over-exposure, diffused light, excessive "heat," vapours or gases in the operating-room, &c.

It is sometimes found that a bath solution after being used to excite a number of plates will yield foggy pictures, although, on testing the fluid, it is slightly acid as at first, and of the proper strength.

How to proceed here is a difficulty not easily overcome. The only plan likely to be successful is to add carbonate of soda until an alkaline reaction is produced, then to filter, and render the filtered liquid slightly acid by acetic acid. Should this fail, making a new bath will save both your patience and your pocket.

Over-exposure is sometimes the cause of fogging, especially when the temperature is high: here our course of action is apparent. Excessive temperature in the operating-room will often give rise to fogging, and is one of the many difficulties met with in a hot climate. Still, with care, we may prevent it by diluting the collodion with one part alcohol and two parts ether — by an increase in the amount of washing the film after exciting — by diluting the albumen mixture with one-third, and the developing solution with an equal bulk of water.

Diffused light in the operating-room is certain to cause "fogging." To test if the operating-room is sufficiently free from actinic light, expose an unwashed and excited plate in the room, near the source of light, for eight or ten minutes, then pour on the developing solution for half a minute, wash and fix with hypo'. Should the room admit no actinic light, and the bath be in good condition, the plate will be quite transparent; but if a foggy deposit has taken place the room or the bath is at fault, and if the former, an increased thickness of yellow calico or another pane of yellow glass must be used.

The vapour of ammonia or sulphuretted hydrogen, in the operating-room, is often the cause of "fogging," and must at all times be most carefully guarded against.

Want of Intensity. — This may arise from many causes. The most frequent in Fothergill's process are — defective bath, too much washing after the exciting bath, and over-exposure.

A defective bath often gives rise to a want of intensity, due to an unknown change which sometimes takes place in the bath solution; and, as no remedy is at present known, the employment of a new bath is the only chance of success.

Too much washing, after exciting, often gives rise to a want of intensity in the resulting negative, more especially if the collodion employed yields a compact film; and for this reason it also appears advisable to use a porous film, heavily charged with iodide. An excited plate — stereoscopic size — coated with Powell's collodion, is, I find, sufficiently washed with six drachms of water, whereas a compact film requires a much larger quantity, and there is more danger of the washing being carried too far.

Insensitiveness. — This fatal difficulty arises from the employment of a very acid or unsuitable collodion. The bath should contain (as before stated) forty grains of nitrate of silver to each ounce, be carefully saturated with iodide of silver, and give a very slight acid reaction to test-paper. To avoid "insensitiveness," or want of uniform sensibility, I adopt the following plan, supposing two dozen plates of first-rate quality were required: — We should here require, at least, four ounces of iodised collodion, and twenty-four ounces of bath solution, and test these by taking a view near the operating-room, by the "wet process;" and, if everything work satisfactorily, fill the bath (holding, say, twelve ounces) with bath solution, and pour off two ounces of the iodised collodion into a clean four-ounce bottle, and use this to coat and excite the plates; then add to the remainder of the two ounces of collodion about twenty drops of ether (more or less, according to temperature), and coat and excite six more plates. Having coated and excited these twelve plates with the two ounces of collodion and twelve ounces of bath solution, it is advisable to turn out the collodion and bath solution into stock-bottles, for further use after being tested, and to coat the second dozen of plates with another two ounces of collodion, and excite them in a fresh quantity of bath solution, of course taking care to add a small quantity of ether to the collodion after coating six plates as before.

This plan ensures uniformity, and is not more expensive in the end than if we attempt to economise by using a limited supply of collodion and bath solution, as the collodion and bath solution may be again used — the former after being slightly diluted with ether, and the latter strengthened if needed.

Stripping off of the Film.—It sometimes happens, on fixing a negative by many of the dry processes, that the film becomes detached from the glass, and slips off in washing. To avoid this, take a small-size camel's hair pencil, and tie it to a thin slip of wood so that the latter may project about one-fourth of an inch below the brush. Dip the brush so prepared into your bottle of negative varnish, and then, holding it upright and using the projecting slip of wood as a guide, carry the brush round the four edges of the plate, so as to leave a film of varnish about one-eighth of an inch all round.

This brush requires to be kept in a separate bottle containing a little alcohol, in order to prevent the varnish on it becoming hard and dry, and thus rendering it unfit for use.

The film of Fothergill's plates sometimes peels up at the edge, on the final drying, before varnishing; and, as this defect often accompanies a good collodion, we must prevent it by an extra roughening of the edges of the glass with a corundum file [the instrument was here exhibited], and when the plate is dry, after exciting, varnish around the edges as before described.

Pin-holes in the Skies.—These minute holes sometimes exist to such an extent as to spoil an otherwise good negative, and may be prevented by fully saturating the bath solution with iodide of silver, and avoiding a collodion iodised with impure iodide of potassium, and using very carefully-filtered developing solutions.

ON REMEDYING THE EFFECTS FROM "COCKING" THE CAMERA.

By W. Russell Sedgfield.

I was glad to see your remarks relative to a patent taken out by somebody for a new stereoscope for presenting the print to the eye in an inclined position, in order to correct the convergence of the perpendicular lines which is sometimes seen in architectural subjects. I did not know that there was anything novel in this. I have often looked at slides in the manner described, and have shown the method to friends. In the open forms of stereoscope, like Mr. Bennett's, this is readily done by simply inclining the picture; but I see that the patent "includes the application of the above principles to the stereoscope, in whatever manner the print may be presented to the eye in an inclined position." Can you tell me if I shall render myself liable to an action if I don't put the slide flat on its back?

There is, however, another method of viewing such pictures, with which the gentleman was unacquainted, or he would surely have patented it too, and which in some cases gives a much better effect. I enclose a stereoscopic slide of the spire of Salisbury Cathedral in evidence (such of your readers as are curious to see it can obtain it at Mr. Bennett's), in which the camera was cocked at an angle of more than forty-five degrees. This does not look natural by simply inclining the picture, but if, in viewing it in the stereoscope, you raise the instrument, *so as to look sky-wards*, just as if you were standing nearly under the tower and looking up at the spire, the effect is remarkably good. An open stereoscope is best, as in the common closed form the light is not sufficiently strong.

But a more immediate object in troubling you with this communication is to explain a method (before somebody patents it) of taking pictures of buildings with perpendicular lines which cannot be photographed without cocking the camera. It consists simply in copying the negative so taken, and in doing so, placing either it, or the plate on which the copy is being taken, or both, in such an inclined position as to bring the converging lines to the perpendicular. The first result is of course a transmitted positive on glass (or it might be taken at once on paper with a Woodward solar camera or other similar arrangement). A printing negative is then taken from the positive. Probably, when the cocking is considerable, the inclination of the plate in the first copying should be only half of what is required, and the correction be finished in the second operation; and if the original negative is taken with an ordinary landscape lens, and the copies with an orthoscopic one, the contrary qualities of these lenses would produce a picture almost absolutely free from distortion or curvature of the marginal lines. Of course the original can be enlarged or reduced at the same time if required.

[A very excellent idea, perfectly practicable, and sound in principle. Negative and plate should both be inclined and the orthoscopic lens employed as a copying agent. The specimen sent is very interesting, and the effect produced by viewing it as described, that is by looking upwards as one does when viewing the building itself, is very striking indeed. — Ed.]

PHOTOGRAPHIC SOCIETY OF SCOTLAND.

LENS TESTING COMMITTEE.

Some correspondence has taken place between the Rev. Mr. Raven and Mr. Taylor, respecting a statement made by the former gentleman, that he was not consulted as to a word of the report on lenses, which appeared in some of the Journals.

It appears that the report was drawn up several months since, against which Mr. Raven made some objections, which were entertained by the Committee at a subsequent meeting, at which Mr. Raven was not present. No alteration having been made in the report, it was considered unnecessary to again submit it to Mr. Raven.

[We find it necessary to state this much, in consequence of a letter on the subject having appeared in the pages of one of our contemporaries, though intended by the writer to have been withdrawn.—Ed.]

NOTICES OF RECENTLY PUBLISHED STEREOGRAPHS.

Some little time back, while passing along the various frequented parts of the metropolis, wherever there was an available place for the operations of the bill-sticker we were sure to be saluted by the words, "No home without a Stereoscope," accompanied by a florid illustration, from a huge wood block, of a family party busily engaged in inspecting stereoscopic slides by the aid of stereoscopes of wonderful patterns; and, judging from the attitude of a lady in the foreground, we should imagine that the suppositious subjects under examination were of the most interesting character, for no human being could possibly maintain such an uncomfortable position for any length of time unless the mind were thoroughly occupied.

Of course the words quoted are only the prominent feature of some advertisement, doubtless setting forth *where* the said instruments are to be obtained for a mere song, &c., but there may be more of prophecy contained in them than would at first sight be supposed. No home without a stereoscope—possibly! nay probably! not many years hence; but certainly it cannot be long before there is no *school* without a stereoscope. What a splendid means of instruction it presents, and the more one considers it, the more we are impressed with a notion of its value when thus applied. We commend it to the attention of the members of the Educational Institute and College of Preceptors.

How common a thing it is to hear the observation, "it is not easy to describe it intelligibly, but *if you could only see it* you would understand it in a moment." Aye! there's the rub: if you could only *see* it — perhaps it may be something too bulky to be seen otherwise than by going to it—as, for instance, intricate machinery; or too perishable to last for more than a short or limited time, such as some beautiful extotic of the vegetable kingdom in full bloom; or too costly, or too distant, or what not. Now only take a good stereograph of the rare, valuable, intricate, or bulky subject, and, lo! the difficulty of inspection vanishes in a moment, and the distant object is brought literally "under the nose" of the spectator. Seriously, we are so fully impressed with the value of the stereoscope as an educational engine that, were it our lot to be employed in teaching, we should unquestionably avail ourself of its aid at once. Amongst other things, for instance, observe what an immense advantage it would be as an adjunct to geographical study—that bugbear to children (and grown people, too, for that matter), that "valley of dry bones" — but add to it the stereoscope by way of illustration, and, as in Ezekiel's vision, the dry bones "would live and stand upon their feet, an exceeding great army." How vividly could be brought before the mind's eye the peculiarities of mountain ranges, lakes and rivers, hill and valley, and all the specialities which go to make up the physical aspects of a country! and still more readily the inhabitants, the national peculiarities and customs, the natural productions, &c., &c. Geography, as generally taught in schools, is nothing more than barren lists of names, that, unaccompanied by anything tangible, are very rarely retained in the mind, except by a very great effort. Add but the stereoscope with proper illustrations, and that which is now a toil would become a pleasure, and we would answer for it more information would be both attained and retained than is now the case generally, and that in a tithe of the time at present employed.

Our readers will doubtless exclaim—"what has all this to do with newly-published stereographs?" We must plead guilty to a very long

digression, nevertheless it has something to do with the subject, for we have been led into it by an examination of a very interesting and extensive series of *Stereoscopic Views in China*, published by Messrs. Negretti and Zambra, of Hatton Garden, and Cornhill, London. The series consist of about three dozen and a half in number, tastily got up, each one with an appropriate ornamental label, and having on the back a printed description of the subject delineated. Although quoted correctly enough as views in China, they are chiefly confined to the neighbourhood of Canton; but, as a consequence, we are enabled to form a very correct idea of the nature of a place hitherto so little known, and so full of interest to the European. It would not be possible for any one possessed of the smallest amount of intelligence to rise from an inspection of this admirable series without having derived therefrom a very considerable share both of pleasure and profit; and the publishers are fully deserving of the best thanks of the public for their enterprise in procuring such valuable means of information. We sincerely trust and are firmly convinced they will receive substantial encouragement to proceed in a course so praiseworthy by an extensive demand for copies of this truly excellent collection, of which we now proceed to notice some specimens in detail, and will commence with the figure subjects.

Chinese Lady and Attendants (No. 42).—Seated on a stool, with the stem of a tree of gigantic dimensions for a background, is a small-footed specimen of a Chinese belle, though to European eyes there is not much that is attractive about her, with the high cheek bones, eyes deep set and near together, hair all gathered back from the forehead and fastened on the crown into a sort of knot. Her dress consists of a loose robe reaching to the knee, with large open sleeves, and fitting close and high round the throat. The white sleeve of an under garment protrudes from the dress sleeve and reaches nearly to the wrist. A pair of drawers made very loose in the leg, and shoes with immensely thick soles, such as all who visited the Chinese Collection, at Hyde Park Corner, or at the Crystal Palace of 1851, must be familiar with, complete her costume. In her right hand she holds a fan, and in her left a book; while her attitude, though unrestrained, is one not usually assumed by the fair sex in the Western Hemisphere, the left foot being nursed on the right knee. A female attendant stands on her left hand, attired somewhat similarly to herself, though with less of finish about the dress; and on the other side is a bare-footed, rawboned male attendant. The trunk of the tree before mentioned is of itself a curiosity: it spreads out at the base, being furnished with what woodmen call "spurs;" but although the thre efigures are not very close together, some notion of its size may be conceived of when we state that it forms a background to the whole of them, and projects beyond the group some distance on one side.

Portrait of Tseang Keun (No. 39).—This, the Tartar General-in-Chief of the army of Braves, is seated on a chair of state, attired in the full-dress costume of a mandarin, which is too well known to need description. On a table by his side, on a sort of stand, is placed his mandarin cap with the red button. The expression of countenance is intelligent, but the attitude a little stiff. Various singular-looking plants in flower, and growing in China vases, are disposed somewhat symmetrically, and the whole is pleasing and extremely characteristic, the background consisting of a quaint trellis work.

Portraits of Pey Kwei and Mr. Commissioner Park (No. 38).—The Governor of Canton and the British Envoy are seated at a table, while six attendants of the former are standing at the back. Like the last mentioned, this group is also taken in a species of verandah or conservatory, flowers in vases being disposed around, and the trellis, resembling irregular hexagonal network, has thrown a shadow on the countenances of the Chinese figures which produces an exceedingly grotesque appearance. Our own countryman being seated with his back to the light has escaped this disfigurement. This, like the last slide, is one of very great interest.

Pa tah lom boo (No. 41).—A Tartar brigadier-general, mandarin of the blue button, is in the centre of the group, and around him are disposed some of his children and other members of his family, with the reverend chaplain of the British army in Canton.

Group of Sailors (No. 40).—This slide is interesting on account of the locality, the garden of the Allied Commissioners, Yamun. Although exceedingly different from an European garden in appearance, it is highly picturesque. On the left of the spectator is a tree of very singular aspect, the stem of which consists of an immense number of branching and anastomosing parts twisted and matted together in the most extraordinary manner. A large-roofed building, open on all sides, and protected by a grove of trees, is, no doubt, designed with a view to obtaining shelter from the sun without obstructing the free current of air.

The Landing Place (No. 6).—This is a small wooden jetty, supported on wooden piles driven into the bed of the river, upon which are seen several natives *squatting* in what appears to the English eye a very fatiguing and comical attitude. In the river are seen several structures that look like small houses, supported on wooden stakes, and in the foreground are a palaquin and the two bearers also *squatting*, but in this case with their knees and chin in contact, and the hands clasped round the knees: with the large mushroom-shaped hats, they present a very droll appearance. This will no doubt be a favourite slide, as well for its novelty as for its picturesque effect.

(To be continued.)

NOTES OF A PHOTOGRAPHIC TOUR IN THE HOLY LAND.

No. X.

Man proposes and God disposes. I write this from Haifa, or Caipha, which lies at the outlet of the River Kishon and the Plain of Esdraelon. It is the modern village which has taken the place of Saint Jean d'Acre, known in the times of the crusades as Ptolemais — a small and filthy place, which possesses no interest except as the probable point which will one day be connected with Jerusalem by rail, if there be ever a railway laid in Holy Land.

Acre, ruined and desolate, stands on the seashore in solemn and stately grandeur. There is an interest that no words can convey an idea of always clinging to such a spot. From early Christian days this spot was regarded as the key of Palestine; and, indeed, long before the days of Christ the Plain of Esdraelon, which here finds an outlet to the sea in the waters of the Kishon, was celebrated as the battle-field on which the nations who invaded Palestine conquered or were defeated. Here Sisera, in the ancient years, was driven to flight; and here Napoleon, but yesterday as compared with the other, with a small troop of men, conquered a host of dusky foes. There has not been a century, for three thousand years, in which there has not been some battle fought on the plain near Acre. The old city seems to know the splendour that hangs around her decay, and sits as proudly in the sunshine as if throned as of old and surrounded with stout guards in flashing armour. I took more than ordinary interest in this place, it being the scene of Sir Sydney Smith's prowess, whose physiognomy my own is said to strikingly resemble.

But I have not told you by what chance I came here; and unless I acquaint you with it you may marvel at my eccentric movements. It was in this wise. When I returned to Jerusalem, from that last evening on the Mount of Olives, I found in the little hotel a party of Englishmen who had recently come from Alexandria. They had been in the city a few days before, while I was away at Nablous, had gone down to the Dead Sea, and were now on their way back to Jaffa, intending to take the steamer thence for Constantinople. This is the common and easiest way of visiting Jerusalem. Come in the weekly steamer from Alexandria, land at Jaffa, ride up to the Holy City, visit Bethlehem, the Dead Sea, and Jordan, and return to Jaffa in time for the next week's steamer up the coast.

My route was laid out. Go over to Cæsarea and up the coast to Mount Carmel. Next morning we rode out of Jerusalem together before daybreak, paying our sleepy guard our last backsheesh for opening the Jaffa gate. Before we reached Jaffa, the temptation to continue in English company was irresistible, and I changed my plans entirely. You cannot imagine the exceeding pleasure of that long talk with old friends. The hours flew by like minutes. Could you appreciate it you would understand how ready I was to change.

A few directions to Hassan sufficed. I ordered him and all the men, with the baggage and tents, to proceed up to Beyrout by the coast road, passing the nights at fixed places which I named. John and I joined the party for the steamer, to go by sea to Beyrout, for the sake of two days more in their company. We found the French steamer at Jaffa in the evening of our arrival, and went instantly on board.

The French steamers on the Mediterranean are a very rough class of vessels. Still, in pleasant weather, with the hatches open, and the ladies in good health, the dinner table presents a gay scene, and there is some fun in listening to the good and bad French, the mixed Arabic and Italian, the English, Spanish, and German, which the various lips and throats utter.

The *Tarbucket* is a miserable fourth-class tub, with no deck-room, and the same amount of cabin. The chief officer is the steward, a withered little Frenchman, who commands the captain, and is sworn enemy to all passengers who are not sea-sick. The

bill of fare of all the French steamers is printed and published in a volume at Paris. All *Messagerie Imperiale* steamers, to all parts of the world, are said to have the same bill on the same days; and as there are some fifty or seventy-five steamers afloat in various services, it is consolatory to know that there is plenty of company in the misery of the most wretched food that could be contrived for the stomach of a sea-sick man. The nominal commander of the *Tarbucket* has had a few private dishes of his own on the table every day, which he sometimes divided with the mail agent — a gruff, grey, tall, thin man, whose lessons of politeness have been learned, and badly learned, in the Faubourg St. Antoine. The doctor of the ship is a little fellow, given to drumming on a piano in the ladies' saloon, and to eating enormously of the vile stuffs concocted between the steward, the cook, and the proprietors of the line. Such is the list of the ship's officers. The working master speaks some English, such as it is. He is a tall, good-looking fellow, and a gentleman withal. But for him, I verily believe, we should have been utterly used-up in the three days voyage from Jaffa northward.

The morning after our arrival at Jaffa the steamer was detained, and we went on shore, to be recalled by a gun when she should be ready to sail. We passed the day in looking at Jaffa, which I have before described to you. Externally it is both common and unclean, the haunt of Gentiles and Jews who are alike beyond the reach of even the Catholic preaching of Peter.

The gun was fired at three. A boat waited for us at the landing stairs. Pushing our way through the crowd of beggars that thronged the platform, we sprang in and shoved off; but by some accident John was left on the platform, and his shouts reached my ear just as we were dashing through the narrow channel in the reef, into which a westerly breeze was now rolling a heavy sea. Backing all, and swinging in on the top of the waves, we had well nigh been upset; but another boat astern of us was in worse condition, for, as we went in towards the stairs with the dash of the sea, she shot across our track most recklessly, and we cut her down to the water's edge, and swamped her then and there. Dire were the shouts of the Arabs, and furious the demands for payment of damages, on the principle that we were the charterers of the boat we were in, and liable for her acts and accidents. The damaged owner, with his assistants, laid profane hands on John, who was quietly awaiting our approach, which they had no sooner done than they repented most heartily; for herculean John seized two of them by the throat, shook them alternately till they were black in the face, knocked their thick skulls together, and kicked the third — the unlucky owner — into the sea. A howl of fury rose from the crowd of all nations on the platform, but no one ventured to lay hands on the giant. John leaped into our boat, and we rolled alongside the steamer. Rolled, I say, for the sea was short, and the vessel pitched at her anchor, so that the passenger gangway was alternately six feet under and six feet above water. No small exertion of skill was requisite to get on board in a dry skin. You must watch your chance as she came down, leap to the highest possible step before she rolled to port, and if you missed your footing, trust to the Arab boatmen and your powers of swimming. Safe on board at last, the usual row with the boatmen about the pay followed, and was ended by tossing a handful of Turkish coppers into the bottom of the boat, which only served to elicit louder demands for more, inaudible as we ducked down the companion-way to the dinner table.

A dismal row of empty seats there were that day at dinner time, for the sea was heavy, and the smell of the oil most vile. All night we tossed and pitched along, and all the next day and the next night, by the port of Cæsarea and the coast of Holy Land. Once we put back. At times our situation was critical and alarming. We lay-to twenty hours, and it was noon of the third day before we reached the lofty bluff of Mount Carmel, and, passing it, ran into the port of Haifa.

There is never anything so very bad that some good may not come out of it. Even *Francois*, the steward of the *Tarbucket*, did us good when he intended our hurt. He had a sharp eye to his provision-lockers, and always warned his passengers to stay on shore when he could thereby save a few mouthfuls of dinner.

"The steamer will not leave Haifa to-morrow!" This was his announcement as we were going down the ladder into a boat to go on shore.

"And why?"

"There is a Turkish Pasha, with his family, coming on board; and he has paid extra to have the steamer wait a day!"

"And we must wait his pleasure? Is that the way of doing business in a French steamer?"

"If Monsieur wishes to complain, there is a complaint-book in the cabin; but, perhaps, Monsieur will save himself the trouble, and have more time to go to Mount Carmel?"

The idea was good, and we improved it by visiting the convent on the mountain, where they preserve the memory of Elijah and Elisha.

It was a long and pleasant day. Climbing the sides of the hill, visiting the old monks in their mountain home, where they rest in calm looking out over the tossing sea, and then, when we saw a cloud, somewhat larger than a man's hand, on the western horizon, hastening helter-skelter down hill more furious than Ahab, and not so fortunate; for he escaped the tempest, but we got soaked and drenched long before reaching Haifa, and came on board ship in the evening fit subjects for the sympathies of the Royal Humane Society. D. T.

Meetings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The November meeting of the above promising young Society was held on the evening of Thursday, the 17th ultimo; the Rev. F. F. Statham, B.A., F.G.S., President, in the chair.

The Chairman having laid before the meeting a programme of the evening's proceedings, called upon the Secretary to read the minutes; which were confirmed. Several donations were then acknowledged.

Mr. Leake, Jun., presented the Society with a capacious wooden folio, and stated that if the gentlemen present would *only* fill it, he would have another ready to present to the next meeting. He also placed within this folio its first photographs, as an additional gift.

Mr. Hannaford gave several specimens of various printing processes. Mr. Howard added half-a-dozen very beautiful stereographs as specimens of the Fothergill process; and Messrs. Cotton and Wall contributed a few other photographs.

Mr. Wall, the hon. sec., pointed out the various articles exhibited in the room, among which were *a camera-stand* for out-door work, by Mr. Howard; *some very fine stereographs* (Fothergill's process), taken by Mr. Archibald Burns, of Edinburgh, and exhibited, with a number of other curious and interesting slides, by the Secretary; a new, singularly portable, and very complete stereoscopic *camera and dark slides* for the dry processes, by Mr. Clark; a very light camera (by the same gentleman), portable and capable of being packed into a very small compass, intended for large views.

A very compact set of apparatus was brought forward by Mr. Hannaford, as used by himself for out-door work.

Mr. Smith, of 16, Mark Lane, exhibited a large collection of rare photographs, landscapes, architectural subjects, copies from paintings, prints, statuary, &c., — taken by Fenton, Caldesi, Bingham, Melhuish, A. Watts, Bisson Frères, and others—a selection chosen with extreme taste and excellent judgment.

A photographic coloured copy, by a native artist, from China; several stereoscopes, and other articles, were also exhibited.

Votes of thanks were awarded severally and individually to Messrs. Leake, jun., Howard, Hannaford, and Cotton and Wall, for their prompt and kind donations, and also to the various exhibitors.

Mr. W. Ackland, vice-president, then read a paper on *The Difficulties of the Dry Process*. [See page 295].

Mr. Ackland resumed his seat amidst expressions of applause.

The President rose to thank Mr. Ackland for so very useful a paper. He had been pleased to hear of difficulties rather than impossibilities, and to know that defects were not without remedies. The specimens of the various defects which the vice-president had provided to illustrate his remarks were, he thought, wisely produced, inasmuch as, being seen, they would be more readily recognised at any future time by amateurs in the dry processes, when the remedies and precautions Mr. Ackland suggested would doubtless prove of great service. To know an enemy was a good way of vanquishing him. Having run over the memoranda he had taken to give in one view the character, &c., of the various difficulties, the rev. gentleman said the references which had been made to some of the photographic publications proved their great value; and concluded by awarding to Mr. Ackland the usual vote of thanks.

Mr. F. Howard said Mr. Ackland's paper was, in his opinion, an invaluable one, pointing out as it did means of removing the many difficulties which beset the dry collodion worker. He would venture to make a few remarks: and, first, with regard to blistering, he would state that, judging by his own experience, it proceeded invariably, in Fothergill's process, from using the glass when it was

not perfectly dry (the collodio-albumen he did not follow); he would therefore advise operators not to be content with merely cleaning their plates well before using, as when they had been put by for any time they required friction (or warming) to remove what he might term an imperceptible moisture, which glass was apt to retain even when kept in a dry room. The breathing upon the glass which photographers adopted to ascertain its cleanliness ought always to be succeeded by a brisk rubbing or other means of warming the plates. As regards water markings, which were among the greatest obstacles to successful results in Fothergill's process, he had succeeded in entirely removing them. He had found in the course of numerous experiments in various collodions that these markings invariably occurred with greater distinctness on one half of his stereoscopic plates than the other, and that half was the one over which the albumen last travelled. It then occurred to him that the albumen when applied after washing the plate had sufficient density to push all moisture before it to a certain point, about two-thirds the length of the plate, when, becoming diluted and no longer able to assert its supremacy, from that point an uneven coating was formed, and the markings began. To avoid them he proceeded in this manner: — after the plate had been removed from the bath, washed, and drained for half-a-minute, he applied the albumen along the long edge of the plate, allowing it to travel slowly right across; it thus had only three-and-a-quarter inches to pass over instead of six-and-three-quarters, and found that by so doing the result gained had been a total absence of the annoyance.

Mr. Ackland, in reply to Mr. Howard, and in reference to the water markings, stated that he invariably found that the markings were not (in his experience) at the bottom but at the top of his glass, and that therefore, in his case at least, the remedy pointed out by that gentleman would not apply.

Mr. Howard also stated that he could produce good pictures with any good negative collodion, want of sensitiveness being the only drawback to the use of such as were not specially prepared for the dry process. With regard to the splitting of the film after fixing, it was caused, he thought, by drying too quickly in a current of air, or near a fire. Washing off he prevented by running round the edge after drying, and before exposure, a brush dipped in albumen; he would therefore persuade workers of the Fothergill process not to discard a good negative collodion simply because it was not prepared for the purpose. If a good wet negative could be got by the collodion and bath, a good dry one, with proper manipulation, would be likewise insured.

Mr. Smith made some remarks regarding the use of gutta percha baths.

Mr. Hannaford remarked that one reason for the blistering which occurred in the collodio-albumen process was that the albumen and collodion film expanded in different degrees on being covered with the developer, and great care should therefore be necessarily used in the selection of collodion. Coating the plate entirely with albumen before applying collodion would prevent non-adhesiveness, and also, to some extent, blistering. Water marking, &c., &c., in the Fothergill plates most frequently, in his opinion, arose from not using the albumen sufficiently diluted. He found the white of one egg in half-a-pint of water quite enough. Marbling from careless development would be, to a great extent, prevented if the plan suggested by Mr. Burnett should be found to answer. He should allude to it in a jotting he had prepared for that evening, which, as it related to the subject under discussion, he might perhaps then be permitted to read. Mr. Hannaford then read as follows: —

I am of opinion that the great secret of success in employing dry plates is in thoroughly washing them. The following plan I like best of all I have tried: —

The collodion should contain a bromide and perhaps a chloride in addition to an iodide, for reasons which will presently be seen. The plate after sensitising is dipped into a pan of water and moved about so as to remove *and save* the greater part of the free silver, and afterwards washed in an unlimited quantity of water under the tap. It is then coated with the following, and washed as before: —

Water	Half-a-pint.
White of one egg.	
Iodide of potassium	Quantity immaterial.
Bromide ditto	
Chloride ditto	

The plates in this state are quite insensitive to light, and will keep any length of time. The operation so far may be conducted in broad daylight — a great convenience for those who have not an unlimited supply of water in their operating-room. To sensitise the plates immerse them in a very weak silver solution, the first washing for instance, and allow them to drain and dry without further washing; or re-dip in the nitrate of silver bath, and thoroughly wash. So far this is only a modification of the collodio-albumen process, in which there is nothing new. The plates in this state will not keep any length of time. This is owing to the presence of free *nitrate* of silver. Plates to be sensitive must have a considerable quantity of free silver present; but it need not be the *nitrate* or any other soluble salt. Bromide, chloride, acetate, citrate, oxalate, &c., &c., answers equally well as regards sensitiveness, and far better as regards keeping qualities; and therefore it will be found that by immersing sensitised plates in citrate, acetate, or hydrochlorate of soda, &c., and afterwards washing them, enables us, without risk, to leave much more free silver on them than when it is in the form of a soluble salt.

Mr. Burnett states that plates prepared in this manner require no silver to be added to the developer — a matter of some importance in the case of long development.

The reason for adding bromide and chloride to the collodion will now be understood; for an iodised plate is sensitive when bromide, chloride, or other salt of silver, soluble or insoluble, is present; and it matters not whether this salt be formed in the collodion at the same time as the iodide, or precipitated afterwards. By adding the salts to the collodion we obtain an evenly sensitised plate with more certainty than by partial washing and precipitation on the film.

Mr. Howard made an inquiry with reference to the exposure.

Mr. Hannaford: The same as for Fothergill plates with like collodion; but as acetate or citrate of silver on the film gives increase of intensity, collodion of a different nature may be employed, and greater sensitiveness secured.

Mr. Martin thought the blisters spoken of had their origin in damp plates, recommended warming over a spirit lamp, and explained his reason for this opinion. The exposure also was, he thought, of great importance in avoiding the defects arising from developing too quickly, &c.

Mr. Leake: I think it a good plan, at least in the wet process, to warm the plate if the atmosphere be at all damp. As I have not practised the dry process to any extent, I do not feel competent to say whether damp glass may originate blisters or not; but it is very probable that Mr. Howard may owe his great success in the dry process in some measure to the warmth obtained from friction in polishing his plate immediately before use.

Mr. Herve pointed out the danger of the electricity obtained by friction attracting floating particles of dust.

The President then called upon Mr. Hannaford to read his promised paper.

Mr. Hannaford said:—

Mr. Chairman and gentlemen, as there are very many matters constantly recurring in every one's photographic experience which, without being of sufficient consequence to form one entire paper, are yet worthy of being "jotted" down, I bring you the first instalment of a series of short papers to be introduced from time to time by one or another member under the head of

PHOTOGRAPHIC JOTTINGS.

No. 1.

The first I will offer is upon *Carbon Printing*.

M. Asser, of Amsterdam, has recently published a process of printing in lithographic ink. I will shortly state it for the benefit of those who may not have read his instructions. [For particulars detailed see page 283]. Mr. Shadbolt, in The Photographic Journal of the 15th inst., in noticing this process states that he has for some time entertained a scheme founded upon one of the photo-lithographic processes, in substance the same as that of M. Asser.

I have not had time since the publication to try either of the above; but I will give you the result of some experiments I made last year in a similar direction.

Mr. Sutton once stated that if a piece of paper be coated with gelatine and a roller charged with printing ink passed over it, on after-immersion in water the whole of the ink would come off, and the paper appear quite clear. Acting on this hint, I took a sheet prepared for iron printing, that is, coated with bichromate of potassa, ammonia, citrate of iron, and albumen. I employed this because I had it by me, and, after exposure under the negative, gave it a coating of printing ink *before* fixing in water; but although I succeeded in getting the high lights perfectly clean, and indeed produced a very fair copy of an engraving, I could not manage the half-tones. A little perseverance might have overcome the difficulty, and I purpose renewing my experiments. In

a second case instead of ink I used plumbago, blackening the paper with it after exposure, but was not over successful. The following plan answered better:—The sensitising mixture had sufficient albumen, gelatine, or gum with it to give a glaze when dry. Exposing and fixing in water as before described, I obtained a print sized in the parts which had come under the influence of light, but unsized in those portions protected from it. When dry it was coated with plumbago by the help of a soft stump. Holding before the steam from a kettle caused the size to retain the black-lead in contact with it, whereas the whites being perfectly unsized the plumbago was easily removed therefrom by using stale bread; friction is, however, objectionable.

I will now offer a few suggestions respecting the above process of M. Asser. In the first place it will require delicate handling, to say the least, to pass an inked roller over plain paper saturated with water so that no ink may adhere to it: perhaps first soaking it in strong alkali, so as to remove any substance having an affinity for grease, would be an advantage. Finger marks, for instance, might be imperceptible to the eye, but they would show as soon as they came in contact with the ink. This difficulty, if indeed it proves one practically, would refer more to Mr. Shadbolt's process than to that of M. Asser; for the latter sized the surface of his paper with starch, which appears a matter of some importance. If used very thick, so as to form a crust on the paper, it would have more the properties of lithographic stone.

The graduated drawing-boards sold by artists' colourmen have a surface of body colour which might render them of use in this process; they may be procured plain, of a very light colour.

One hint more and I have done with the subject for the present. Lithographic printers are in the habit of mixing gum arabic with the water to keep the stone damp, as it is found to repel grease much more completely than water alone. It might be advantageous to add gum and, perhaps, a little nitric acid to the water with which the paper is kept saturated whilst being inked.

Photo-engraving.—As hints on this subject are always acceptable, I give the following very rough "jotting" of a process by which I think something may be done. Last spring I coated a steel plate with the iron solution used in my iron printing process. Bichromate of potassa and gelatine answers the same purpose. The exposed plate was immersed in nitrate of silver, when chromate of silver was formed on the parts which had not been acted on by light. The plate could now be bitten into by acids, hydrochloric for instance.

If instead of steel a copper plate be used, and after immersing in the silver it be washed so as to remove the film, an impression is obtained somewhat resembling a daguerreotype, reduced silver giving the shadows and the unaltered copper the lights.

Mr. Howard: As regards the want of half tones in the method of carbon printing alluded to by Mr. Hannaford, having had considerable lithographic experience, he could say that half tones were not to be produced on a smooth surface. If you pass the lithographic roller over any smooth surface, the ink must adhere to all parts in a uniform manner; that it was necessary in lithography, if you wanted half tones, to have a roughened or granulated surface, as the ink then only adhered to the projecting and prominent portions, forming a series of irregular dots.

Mr. Wall would venture to put forward a singular fact as another "jotting," which in these days, when photographic portraits are received in our courts of law as evidence to prove identity, might not be unimportant, although he would not for an instant infer that such evidence should be doubted. The two photographic portraits he now placed before them were beyond doubt of two perfectly different men, and yet they were so alike that he had much difficulty of convincing many of the fact.

Mr. Leake said, although the hour of adjournment had already come and gone, he would, with permission, detain the meeting a few minutes longer, as he had a communication to make which might prove important. He had been much annoyed by a new sample of glass (patent plate) called German. His usual cleaning solution, consisting of cyanide of potassium and tripoli, had not the least effect, and another plate-cleaning solution, warranted to clean anything, was equally impotent. Both these solutions were perfectly effective with other glasses. He found, also, that the exposure was with this glass much longer. A deposit made its appearance between the glass and the collodion during development, and the picture produced was misty and full of stains. Moreover, after drying, the film in most instances split and came from the plate. He had tried experiments with the same cleaning solution, bath, and developer on the same day, using other glasses, with excellent results.

Mr. Wall said he understood that there was a large and increasing demand for the glass in question; the wholesale houses, he had heard, were buying largely. In his own establishment they had willingly purchased, for it was cheaper and to all appearance better than that they had previously obtained. The matter therefore was one of importance. As he had witnessed Mr. Leake's experiments, he could vouch for them.

Mr. Herve stated that he once met with similar difficulties from purchasing a glass called in the trade "jam glass," and made in Germany. He attributed it to the presence of lead in the formation of the glass.

The President suggested an experiment to test the specific gravity of various specimens, with reference to their photographic qualities, and then announced for the next meeting, on Thursday, December 15th, a paper entitled *Practical Observations upon Photographic Productions in their relation to Art*, by Alfred H. Wall, Hon. Secretary.

Mr. Leake promised to fill up any space which might be left unoccupied, by bringing down a few more "jottings."

The following gentlemen were then elected:—Mr. J. Williams, Mr. T. Clarke, Mr. G. S. Tear, Mr. W. Lovett, Mr. J. Martin.

Mr. Herve proposed a vote of thanks to the Chairman, which was heartily awarded.

The meeting then adjourned.

CALEDONIAN PHOTOGRAPHIC CLUB.

This Club, which was instituted for the purpose of diffusing among its members information on *practical* photography, held its first meeting, in Edinburgh, on the evening of Saturday, the 12th ultimo.

Mr. M'Naughton was called to the chair.

After the usual routine business consequent on the formation of a new body, the following gentlemen were elected office bearers:—

Secretary — Mr. Andrew Wilson.
Treasurer — Mr. Roderick M'Nab.

The Chairman then addressed the members at great length on the peculiar circumstances under which they were now met; and he hoped that, now their little barque was fairly launched under such auspicious circumstances, each member would guard against any act which might lead them into the unenviable position of being regarded as the schismatics of another Society. Indeed, from the well-known characters of the members, he predicted with confidence that this Club would be a great success. He dwelt on the advantage to be derived from that peculiarity of their constitution which prevented them admitting any new member who had not satisfactorily undergone a searching examination in the practical details as well as the theoretical principles of their beloved art, as they were desirous that the practical and useful should not be sacrificed to the merely theoretical and ornamental. Still, while their aim was strictly practical, they would not despise theoretical knowledge.

He concluded by hoping that in any discussions on subjects brought before them, mere speech-making would be avoided, adopting in preference a free and easy conversational style.

Mr. Brown said, I propose that one feature of our meetings shall be, that some member, Mr. Turnbull for instance, shall procure and detail to us an account of what takes place at the meetings of the principal Photographic Societies in Britain—such as the London, North London, Liverpool, and Scottish Societies; and that a sum of money be set apart, if needful, for the purpose of procuring accurate reports.

This was agreed to, and Mr. Turnbull authorised to make the necessary arrangements for carrying out the proposition.

Mr. Wilson said "he was glad to be in a position to give them reliable information as to the recent proceedings of the Liverpool Club [as these proceedings have already appeared in a preceding number of this Journal, we think it needless to reprint them here. Ed]. He could also furnish them with an account of what took place at the last meeting of the Photographic Society of Scotland, procured partly from the local papers and partly from private sources. The chair (according to the *Scottish Press*) was occupied by Mr. Scott Eliot. Mr. Alex. Munro, of Craiglockhart, and Mr. R. Struthers, were elected ordinary members. After the usual formal business, a *conversazione* took place, at which were exhibited several improved cameras, and other photographic apparatus, as well as collections of photographs from Rome, France, and elsewhere. Mr. Walker gave an account of what he saw on a recent visit to London. Stereoscopic pictures seemed to hold the chief place among photographs. He described some portable cameras and tin

preservative cases for excited positive paper which he had seen—some of which cases he (Mr. Wilson) might state were to be laid on the table at the next meeting of the Caledonian Club.—Mr. Walker's remarks were well received, and led to some conversation. The subject then turned on the recent testing of lenses, on which there was some animated discussion. Two of the members of that Committee who were present defended the report in every particular; and characterised the "triplet" form of lens as the best they had tried, notwithstanding that it had been procured from the stock of an optician in this town; whereas some of the others had been procured from the makers, with a special view to this testing. This was a fact that should not be lost sight of. During the evening it was stated that there was every prospect of the Society's exhibition, which is to be opened in the middle of December, in the large room occupied by the exhibition of last year, No. 90, George Street, being the best that has yet been held by the Society. In addition to the works of members, contributions have been offered from most of the photographic artists of this country, and interesting and valuable collections from India and Australia have likewise been promised. The attendance was not very numerous, indeed scarcely more than were now present."

A conversation on this report ensued, in which Mr. MUNDELL said that if he had been on that Lens Committee he should not so quietly have submitted to the would-be-snubbing remarks of one member of the Council of the Society—although that gentleman had had small cause to rejoice in the success of his attack. He thought that this Committee had done much good by causing the subject to be more inquired into. He called on the Secretary to put down his (Mr. Mundell's) name for a paper on lenses at the next meeting of the Club.

The SECRETARY said they would be happy to have his paper, but he was afraid they would not do justice to the discussion on it at the next meeting, as Mr. Williams was to read a paper on *Transferring collodion positives from the glass plates to leather, cloth, &c.*, which was to be accompanied with numerous illustrations; however, if they had time, they might accomplish both on that occasion.

Mr. MONTAIGNE said, you must really allow me a word or two on the Report alluded to. The members of that testing Committee acted a most strange part in saying that the triplet lens (which by the way is scarcely Sutton's triplet after all, for it was made by Goddard, who in his construction of it introduced some *new* features, which, in my opinion, render it superior to Sutton's published description, and susceptible, too, of allowing its being made vastly lower in price)—well, I hold that the Committee had no right whatever to say that this lens gave the best results; for it is a notorious fact that the *best* pictures were produced by that lens, not as it came from its maker, but after it had been disfigured by being sloppered around the edges with black varnish, velvet, &c., which Mr. Tunny, in whose possession a friend of mine saw the lens, assured him had been found absolutely necessary to be done in order to get intense shadows by shutting out the flare from its numerous surfaces. What right then had they to call it Sutton's lens? I hold that this should have been explained in the Report.

Mr. BROWN: I think that Mr. Montaigne's remarks form no case against the Lens Committee. I, too, called and saw the lens, and think the Committee acted wisely in blackening the edges of the glasses, as the lens was said to be one of the first made on that model, and I think such a storm need not be raised against what is such a simple matter. Individually I disapprove altogether of compound lenses for landscapes, preferring the old meniscus form: little or no distortion, even in architectural subjects, is got by it, provided it be not forced by taking too large a picture.

Mr. STEELE: I think it a sheer waste of our valuable time at present for members to be haggling away at the affairs of another Society, against which conduct I protest.

After a protracted conversation on the best way of conducting the business of the Club, it was at length resolved—"That no new member, be his qualifications what they might, should be admitted to the Club, until there was a vacancy in their circle from the death or resignation of any of their members."

Mr. M'ADAM moved that arrangements be made for having an exhibition, and that a medal be struck for a prize to the best artist.

The discussion on this was delayed till next night of meeting.

Also proposed and deferred—

"That the editors of the various photographic periodicals be elected honorary members."

There was a full attendance, and after the usual vote of thanks to the chairman, the meeting separated.

Practical Instructions on Coloring Photographs.

By ALFRED H. WALL.

CHAPTER VI. *(Continued).*

PIGMENTS.

The pigments which are most eligible for water have already been fully described. It is well to become thoroughly acquainted with the power your pigments possess in combination, and a little time devoted solely to the compounding of hues, shades, and tints will by no means be thrown away. Pigments are prepared moist in pans and tubes, and in dry cakes. For large washes I prefer the moist colours, in pans; for the more delicate colours, those in dry cakes; and because the madder pink generally comes too slowly from the cake, and yet must be preserved pure, I choose this moist in a tube. Select the following colours:—

Madder Pink	Gamboge	Sepia
Crimson Lake	Yellow Ochre	Vandyke Brown
Purple Madder	Naples Yellow	Neutral Tint
Brown ditto	Indian Yellow	French Blue
Vermilion	Raw Sienna	Cobalt
Extract of ditto	Burnt ditto	Indigo
Light Red	Lemon Yellow	Prussian Blue
Indian Red	Cadmium	Ivory Black.

For the chemical and other qualities, peculiarities of working, &c., of the above, see the chapter on colours as pigments.

GUM.

A solution of gum in distilled water, one part of the best white gum and seven of water, to which add a piece of loaf sugar about half the size of a filbert.

PREPARED OX-GALL.

This is generally used to destroy the effect of grease on the surface of your paper: it is used with the water.

WATER.

It is essential to obtain this free from such ingredients as would injure your pigments: spring or mineral water would quite destroy the more delicate vegetable colours, therefore use rain or distilled.

PREPARATORY PRACTICE.

To acquire perfect freedom of hand and a dexterous method of using the brush must be your next aim; and to acquire this I do not know that I can recommend any better practice than what is known among photographers as "touching" (which is a method of "working up" photographs on plain paper in indian ink, sepia, or a mixture assimilated to the colour of the photograph). Inasmuch as you will find that errors of execution are more readily detected, and consequently remedied, in the use of one colour than many, I shall therefore include a lesson upon this subject, although I hold that a good untouched picture is greatly superior to the touched, for truth of texture, *chiaroscuro*, and general effect.

The native truthfulness of a good photograph is so superior to the smoothness and laboriously stippled prettiness of an india-ink drawing, that creating the last upon the first seems to me a display of the most erroneous judgment and bad taste. The excuse generally tendered for the "touching" of photographic portraits, or, in other words, for making them resemble india-ink drawings, is, that it gives them *finish*, by which is evidently meant *smoothness*. But Mr. F. Howard shall say a word upon this subject in the following quotation from his chapter upon finish in "Imitative Art":—

"This [finish] does not consist, as appears to be a prevalent erroneous notion of the present day, in smoothness of surface, or tea-boards would be the most finished productions of art. Sir Joshua Reynolds could not be said to have finished any of his pictures; texture would be worse than of no value; but varnish would be the artist's best friend. Nor does finish consist in another kind of smoothness, which results from the careful blending and softening of all the touches, so that the method of execution shall not appear. Nor does it consist in minute detail, but in *the complete expression of character*."

In this sense what can be more finished than a perfect untouched photograph? Does it not indicate in detail every variety of texture, the rough, the polished, the smooth, and all the varied surfaces of nature?

In touching, therefore, aim not to smooth and even up the tints and shadows, but rather to preserve and strengthen every trait in the photograph, more particularly if, as I recommend, you merely commence this branch as an introductory study to that of colour.

A pale print of a cold tone is best, if you intend to finish in india-ink; a warm or cold brown, if you intend to touch with warm or cold sepia; and, if you please, you may compound a tint resembling that of the photograph, which, if it be of the usual purplish-black,

may be got with madder purple and india-ink, or madder brown and india-ink, to which, if necessary, may be added a little indigo, or a little indian-red, lake, or burnt sienna. Let the print be upon plain salted paper — not albumenised.

Having selected your photograph, and mounted it upon Bristol board — which, having a hard, smooth surface, is best for the purpose — size it with parchment size, and let it be "rolled," that is to say, pressed with very great force between cold steel cylinders. Any hot presser will readily do this, and the process not only improves the smoothness of the surface, but so hardens it that it is not easily disturbed.

Your colour mixed (clean water and hair pencils being ready), pin down your picture upon a drawing-board; imagine your teacher at your back — resolve to gratify him, and raise yourself in his estimation, and commence.

With a touch so faint and light that it is only after several applications that you can perceive its effect, begin to strengthen what I will call the outlines — although in a good photograph, as in nature, *there are no outlines.* To put in these *apparent* lines *at once* would be to produce distinct lines, resembling nothing else but lines, which is a very common mistake, not only with beginners, but with some who pretend to professional experience.

The author of the preceding paper has, in order to render his communications of greater practical value, kindly undertaken to criticise the work of, and give advice to, students in colouring, through the medium of these pages, for which purpose specimens may be sent, with a stamped and directed envelope *for their return, to* A. H. Wall, Esq., 11, The Terrace, Walworth.

G. Daintree.—Yes, with much pleasure.

James Pearson.—The print is too dark and too thick for colouring.

Alfred Teague.—The tints are rather too pure. Your progress flatters me.

Ellen Green.—You need nothing but more practice. When the paper is roughened by pumice-stone powder a closer resemblance to crayon drawing is the result; but it is certainly easier to work upon a very smooth surface, which is obtained by hot-pressing. On rough paper the colour is rubbed into the grain — on smooth it is on the surface only.

Poor but Proud.—Did you know you were writing to "a mere photographic colourist?" I hope not; for then this lengthy epistle would be *an insult.* I will *condescend* to give you a more lengthy reply than you deserve, because I recognise you as one of a very large family which we workers in the hive call *drones.*

Why should that which would degrade you not degrade me? Is enervating idleness and mean and unmanly dependence so *very* superior to "the glorious privilege of being independent," that you hesitate to exchange the latter for the former? Examine what you call your "pride:" it had its origin in the possession of a thing which as often dignifies vice and folly as not—viz., money; but you are poor — you have lost the substance, and hope to retain its shadow — you would deceive the world by exhibiting your pride in — *nothing* (for that which was and is your pride exists no longer), in order that the world may believe your nothing to be something, which *in itself* can neither improve your mind, expand your heart, or confer any real honour or advantage. Oh! cease to contemplate the shadow, and eat your bone; and, if you have sufficient talent (which the specimen sent does not however indicate), you may bless the day when, with or without my aid, you became a "mere photographic colourist," and threw overboard both your own scruples and those of your "very highly respectable family." Pardon my bluntness — you will not find me a less zealous instructor.

Letters to a Young Photographer.

No. XXIV.

My dear Eusebius,

You must be careful to keep your sensitised paper out of the influence of light and atmosphere. Some photographers make use of a pressure-frame for that purpose, which answers very well: others employ Marion's preservative cases, which is the best contrivance that I have seen for keeping sensitised paper in. Papers impregnated with wax, gutta-percha, belmontine, or paraffine, do not decompose near so rapidly when sensitised as plain paper does; for these substances not only make the paper translucent, but also protect its fibres from the decomposing action of nitrate of silver. I think it advantageous to put each sheet of sensitised paper between white blotting-paper, which prevents the waxed-paper from creasing when put into a pressure-frame.

If the waxed-paper be put under glass when exposed in the camera, the time of exposure will be prolonged. The paper may therefore be mounted by gluing the edges on to a piece of Bristol board while it is damp; it will contract upon drying, and strain perfectly tight and smooth.

The exposure in the camera will of course depend upon so many contingencies that it is impossible to give any rules, special or general. You may under very favourable circumstances obtain a picture in two minutes, at others in half-an-hour, and on some occasions an hour may be requisite. Only judgment based upon experience will serve you as a guide in this part of your operations. In architectural subjects a tolerably long exposure is necessary to obtain the details which are in shadow. As a general rule, waxed-paper pictures are under-exposed by inexperienced photographers.

After exposure in the camera the developing may be deferred for several days, although it is best to effect it within twenty-four hours.

The picture is generally invisible when the paper is removed from the camera, especially if it has been well washed when removed from the bath; sometimes, however, the sky and high lights are visible, distinguished by a light red tone. Plunge the proof into a solution of gallic acid.

Gallic acid	2 grains.
Distilled water	1 ounce.

Filter, and add about two drops of aceto-nitrate of silver, or two drachms of the water used for washing the paper after it has been taken out of the sensitising bath, and immerse the proof completely in the mixture, facilitating the immersion by the use of a glass triangle. Shallow glass dishes are best for developing proofs: they must be kept scrupulously clean, and rubbed with blotting-paper previous to using them.

The image should develop gradually, and not more than two proofs be put into the same bath, placed back to back; but it is still better to put in only one. The proof must be placed in this bath immediately it is prepared, else it will become covered with a veil of precipitated metallic silver, and lost; therefore the paper should be put into it with the picture downwards, so that any precipitate that forms may fall on the back, from which it can be removed with a weak solution of cyanide of potassium.

As it is very troublesome to be obliged to mix solutions of gallic acid every time they are required, since they will not keep if prepared beforehand, you can employ an alcoholic solution of gallic acid, which will keep any length of time, and add such proportion to water as will constitute a bath of the requisite strength: say two grains to the ounce of water.

You will soon be able to ascertain if the exposure has been correctly timed, by the behaviour of the proof under development. If the development has been too long, the picture appears all over with great rapidity; but it will not take an uniform tone and vigour. This defect is the more to be feared when the layer of iodide of silver is very thin. If, on the other hand, the exposure has been too short, the paper becomes completely opaque before the half-tones have had sufficient time to appear. Such pictures are too harsh in tone and contrast to be tolerable. You may always judge of the vigour of a proof in examining it by transparent light; for, after it has been immersed some time in the bath, the surface of the paper frequently acquires a general grey hue, and you would consequently think your proof lost did you not know that this is a sign of complete success.

The time necessary for the development of a proof is extremely variable, and you must be satisfied if it proceeds slowly. Slow and sure is your motto. It greatly depends upon the temperature and upon the quantity of silver contained in the bath. It may vary from half-an-hour to two hours, or even more. The proof must be carefully watched, especially as it approaches completion, for the blacks increase in intensity very rapidly, and you must stop the developing when the darkest parts, which represent the lights in the positive, have become almost opaque. Upon the just appreciation of this point all the beauty of the proof depends, and you must acquire the power of exercising it by practice. Of course you will have to make some allowance for the weakening the picture undergoes in the fixing bath.

You will stop the developing by taking the proof out of the gallic acid, and washing it several times in filtered rain water, and soaking it for several hours in water, before you attempt to fix it. If the proof be soaked in river or spring water, the latter becomes, after a time, of a deep green colour, arising from the action of the gallic acid upon the salts of lime contained in the water in contact with the atmosphere.

The proof, when dried, after proper washing, is no longer liable to alter, or but slightly; and it may be kept in a portfolio until it is convenient to fix it, which is a great advantage while travelling, as the intolerable hypo' may be for a time dispensed with.

To fix a proof, make the following solution:—

Hyposulphite of soda	8 ounces.
Water	1 ounce.

This bath will dissolve out the salts of silver which do not form the image. It is best to put only two proofs at a time into it, and watch them attentively for about half-an-hour.

This operation should be performed in broad daylight. It must be continued until the yellow colour of the lights of the image disappears. This yellowness is due to the presence of iodide of silver remaining in the pores of the paper. The proof must be washed in filtered water several times on being taken out of this bath, and then allowed to soak some hours, changing the water occasionally. It is then fixed, and may be dried between blotting-paper.

The fixing is a most important operation in this process. The immersion of the proof in the hypo' must be prolonged to the utmost, consistent with the safety of the proof, so as to make sure that all the salts of silver are removed. It often happens that a proof, supposed to be well-fixed, becomes yellow after a time in the printing frame, and, consequently, injures the quality of the positives taken from it. Whenever this happens, the only remedy is to put the proofs into a fresh bath of hypo'. Upon becoming dry the waxed-paper assumes a dull and granulated appearance, not at all captivating to the photographic eye, but it entirely disappears when the paper is gradually warmed at the fire.

The proofs can also be fixed in a bath made as follows :—

Bromide of potassium	1 drachm.
Filtered water	6 ounces.

In a chemical point of view this fixing solution is bad, because it does not dissolve out the salts of silver. It destroys their sensibility, it is true, but it leaves the yellow iodide of silver in the paper, which is injurious to the taking of positives. When the proof is very weak it is, however, better to employ it than to risk weakening it still more by hyposulphite of soda. Bromide of potassium may be replaced by a saturated solution of common salt.

The chief point, as you will see, you have to avoid is that of allowing your proofs to become yellow. This is likely to occur when the developing bath contains too much gallic acid, or when it has become thick from impurities. Hypo' has no effect upon this yellowness, which becomes red in the course of time. They hoist a yellow flag at quarantine-stations when the plague prevails; take you good care not to hoist the yellow flag, else you will be plagued indeed.

Photographic Glossary.

Varnish for Negatives on Glass — Varnish for negatives must possess the following properties: — It must be colourless, dry quickly, and be free from tackiness; not easily abraded or scratched, and not soften by the heat of the hand, or by exposure to the sun; it must be pliant and adhesive, so as not to scale off the glass. And the best resin to secure these results is *lac*, mixed with a small portion of a soft and unctuous resin, such as elemi.

The following formula will answer the desired aim :—

White lac	12 parts.
Elemi	3 ,,
Powdered glass or sand	10 ,,
Alcohol	100 ,,

Put the bottle containing these ingredients, tightly corked, into a warm water bath. When the resins are dissolved, clarify with ivory black, and filter through paper.

Although this varnish may be slightly coloured, it is not objectionable, but rather advantageous, as the half-tones are protected by it, and a clearer proof is the result.

The addition of oil of lavender or of rosemary is not essential, although sometimes recommended. They serve to impart an agreeable odour.

The lac should be first broken into very small pieces, and put into a moderate oven to dissipate all the moisture it is apt to retain in the process of bleaching.

Foreign Correspondence.

Paris, November 25, 1859.

In the present dearth of original photographic discovery, I think I cannot do better than communicate to you an account of M. Robiquet's researches upon the rays of the solar spectrum, and of the various electric spectra. Frauenhofer thought that the rays of the different spectra were dependent on the constitution of the luminous source in which certain kinds of rays were completely wanting. It remained to ascertain the cause of this absence of light. We may attribute it to an effect of interference; for upon receiving the image of a solar spectrum on a screen, and placing before it, very near, a thin plate of mica, none of the rays are modified. So also, if we divide in two one of the two rays H with the vertical edge of the same plate of mica, there is no illumination in the masked portion. The existence of the rays of the spectrum is due to an entirely different cause, which may be explained by the following experiments :—

If, as Dr. Draper has done, we produce a spectrum with a flint prism, and a platinum wire rendered incandescent by an electric current, this spectrum has no rays; but if we place between the prism and the wire a glass cylinder terminated by parallel plate-glass faces, and filled with the vapours of hypo nitric acid, the rays immediately appear. Supposing Frauenhofer's spectrum to be superimposed on the preceding, we perceive the new rays disposed as follows :—

Extreme red (B and C).—A group of very fine rays, very numerous, and nearly equidistant.

Red (immediately after C).—Two very clear rays.

Limit of the orange and yellow (a little before D).—Four distinctly marked rays, especially the third. The ray D is found in the new spectrum, and is the only one among Frauenhofer's rays that is.

Yellow (between D and E).—Three equidistant rays.

Greenish yellow (a little before E).—Two very strong rays.

Green (between E and F).—Two groups of very fine and compact rays, forming rather two obscure bands.

Bluish-green (before and very near F).—A group of very fine, numerous, and clearly visible rays.

Blue-violet (F and G) and *violet* (G and H).—Six groups of numerous, almost invisible, rays.

In substituting the vapour of iodine and bromine for the nitrous vapour, the rays change their nature again. With dry chlorine there is not the slightest appearance of rays. Even with a tube fifteen feet long there is only a light illumination in the green part, and especially in the yellow portion of the spectrum.

The effect obtained by the platinum wire is also produced by other metals; those experimented with being iron, silver, gold, aluminium, copper, sodium, potassium, and chromium. All these metals were melted and volatilised by the current of a strong pile by suddenly breaking the interpolar communications, and the incandescence continued long enough to admit of the phenomena being distinguished, if not analysed. These observations confirm the anticipations of M. Foucault, who, in remarking that the spectra from the carbon points brought to a white red exhibited no rays, and concluded it must be the same with all incandescent bodies.

Other experiments agree perfectly with the preceding. When we observe the spectrum produced by a horizontal gas jet, and by means of an opaque screen furnished with a very close shutter, and arranged in such manner as to allow only the blue portion of the rays to fall upon the prism, we see the ray D very distinctly, two fine green rays separated by a black band, three blue rays, and lastly, four violet rays. The same phenomenon is produced, but very much feebler, with the brilliant portion of the flame. Upon repeating the same experiment with a gas jet pierced with twenty holes, furnished with a glass chimney, only the feeblest sign of rays can be distinguished, in whatever way the brilliant or the blue portion of the flame is placed.

The appearances that the spectra produced by the metals volatilised under the influence of the electric current are extremely curious, and the theory of the preceding phenomena is entirely applicable to them.

M. Foucault, in a memoir published in 1849, has studied these spectra in a general manner, and arrived at very important results. M. Robiquet began by repeating M. Foucault's experiments, not with the view of verifying their accuracy, but to accustom himself to such delicate observations before proceeding to examine the metallic arcs, the spectra of which had not yet been examined. The following are the appearances presented by the arcs of the following metals : —

Platina. — Burnt with a white light. The ray D existed. All the parts of the spectrum were covered with very narrow black bands, allowing the different colours to be seen between them as between the slats of a Venetian blind: these interstices appeared as very large brilliant rays, among which could be distinguished, in the following colours,

Red, six rays; *orange red*, three rays; *green*, four groups of very fine rays; *indigo*, two rays. All these rays possess dazzling splendour. In the *violet-blue* ray an absorption almost complete

was observed: in the *violet*, three very luminous large bands, and in the *extreme violet*, two large dark rays, corresponding to the two rays H of the solar spectrum.

He also operated with aluminium, gold, chromium, copper, silver, sodium, potassium, strontium.

The photographic representation of all these spectra is difficult, except with silver and sodium; the metallic arc has so little steadiness that there is the greatest difficulty in obtaining images in which the rays are not every moment displaced.

We cannot give iodised collodion an exposure of more than four or five seconds, insufficient to obtain an impression of the magnificent ray D from sodium, the blue rays from aluminium, the two green rays from silver, and the magnificent red bands from chloride of strontium. All these colours are very slightly photographic, notwithstanding their brilliancy; but starting from the last violet rays, two or three seconds suffice to obtain a satisfactory negative, and, what is very remarkable, we observe in this spectrum, which is invisible to the eyes, but which so strongly impresses the iodide of silver, rays and bands which remind us, by their arrangement, of the coloured part of the spectrum to which they belong.

The brilliant rays of the electric spectra produced by the different metallic arcs must not be confounded with those of the spectra engendered by the electric spark, and which are due, as M. Masson has shown, to the material particles brought by the electric flux to the state of incandescence and transported through the space which separated the extremities of the conductors. It may happen that rays from the carbon arc are only secondary rays, due to the separation of the silicious particles which always exist in so large a quantity in the best prepared crayons.

Lastly, photographic proofs were obtained of the solar spectrum produced by a system of lenses and prisms: first, of rock crystal; second, common flint; third, Faraday's flint. In the first case all the obscure rays were temporarily seen; in the second, nearly one half were wanting; and in the third, almost all.

The conclusions to be arrived at from the above are, that every incandescent body, whatever its chemical nature, gives a spectrum without rays; if this body, in volatilising, surrounds itself with colourless and transparent vapours, still the rays do not appear; but if the vapours produced are heavy, quickly condensable at the ambient temperature, and still more, if they are at the same time colourless, they intercept a portion more or less considerable of the total radiation.

To explain the action of these vapours, it is best to compare them on a screen in the form of a grating, the bars of which, unequally spaced, must be of considerable diameter, and of extreme thinness. In the first case, the shadow projected shows itself in very fine dark rays (rays of the solar spectrum); in the second, the masked rays are in considerable number: true obscure bands are produced, in the interstices of which the luminous and coloured parts appear as brilliant bands or rays (spectra of the metallic arcs produced by the pile).

When the spectrum is formed by the incandescent particles transported mechanically, either by the electric flux of the pile or by the spark, brilliant secondary rays appear, very easy to recognise by their intermittent character.

The invisible portion of these different spectra undergoes the same effects of absorption as the visible portion, and the effects may be rendered visible by photographic processes.

M. Robiquet fully understands that this task is far from being completed, and he hopes to be able to devote himself to its study, being so nearly allied to that of the nature of light. It is necessary to construct special delicate apparatus to enable him to count with precision the rays of the different spectra, and measure the reciprocal distances, and to obtain by processes still more delicate and sensitive photographic proofs of all the parts, visible and invisible, of the spectra, produced by the light of the stars, and by the electric light. J. P.

Correspondence.

TONING.

To the Editor.

Sir,—Would you be so kind as give me the best formula for Mr. Maxwell Lyte's toning-bath? I am in the habit of toning about four prints, eight-and-a-half by six-and-a-half inches, daily. I employed the formula given in the March number of the Journal, but to soak a print in that solution, say five ounces, and not use it a second time, is very expensive.

To use the alkaline toning—gold one grain, soda ten grains, water five ounces—produces red spots in the paper, and upon adding the hypo' the print loses all brilliancy. Before I toned the enclosed print it was all I could wish it to be. Out of the last quire of paper I may say I have not had one good print. I have toned some excellent pictures with the same formula, but the two last quires of paper produced results like the enclosed. If you can spare a few lines in the next Journal I shall feel obliged.—I am, sir, yours, &c. M. A. H.

[Dissolve eight grains of chloride of gold in half-an-ounce of distilled water. Neutralise any acidity by adding solution of carbonate of soda, then make up the quantity, by the addition of water, to one ounce—each fluid drachm will then contain *one grain* of gold salt, which will be quite sufficient to tone you four proofs.

When about to operate measure out the quantity of water that you find sufficient to allow of your prints being comfortably immersed, then dissolve therein about thirty grains of phosphate of soda, and add to it the drachm of gold solution. Immerse the proofs, after washing out the free nitrate of silver, and allow them to remain till properly toned, then fix.

No doubt it is the paper that you have been using that is in fault; but you must remember that a free alkali dissolves out the size, which the phosphate of soda does not. We notice also that the tone of your specimen is cold and flat: this may be partly owing to too long immersion in the gold bath, from which it should be removed as soon as a full purple hue is acquired; and although it may look reddish after the fixing bath *while wet*, you will find that on drying it becomes blackish.—Ed.]

STEREOSCOPY.

To the Editor.

Sir,—Having very frequently met with individuals who do not see equally well with both eyes, I begin to believe that there are few persons in whom the sight of one eye does not differ from that of the other—often in focus, but more so from defect in vision; hence, while so much is said of the beauty presented by pictures as seen through the stereoscope, the number of those who can appreciate this beauty is exceedingly limited. Many do not know that they possess this defect, till by some chance it is revealed to them; others know, but do not admit the fact, as no difference, without minute examination, can be discerned in the appearance of their eyes.

The business now for all who believe in the stereoscope is to examine their eyes, and if the truth is told, I am satisfied that the question I have advanced will no longer be doubtful.

I am yours, &c., R. S. D.

24th November, 1859.

[We do not perceive that the allegation "that there are few persons whose eyes are both of similar focus," even if well founded, affects the question at all.

The stereoscope presents pictures to each eye, as in nature, or should do so. *If* natural objects are viewed by eyes differing in their focus, so should stereoscopic ones be viewed.—Ed.]

WHICH IS THE *BEST* PRESERVATIVE PROCESS?

To the Editor.

Sir,—I am an amateur photographer, desirous of ascertaining which is the best preservative or keeping process.

From the flaming advertisements and accounts published in the various journals relative to some of the keeping processes I have been induced to try first one and then another; but I have not found the results come up to the accounts given of them.

Now, Mr. Editor, I do think you would be rendering photographers great service if you could induce some of the parties who "write up" their processes so highly to show the public, at the next Photographic Exhibition, *some of their works;* for I must confess that, although I *read* and hear very high characters applied to certain of the dry processes, I have hardly ever seen photographs by them even come up to mediocrity, but certainly bearing no resemblance to the pictures we are led to expect.

In going through the catalogue of the present year's Photographic Exhibition I find only five exhibitors (out of nearly one hundred) who operate by the dry or keeping processes on glass—viz., one by the oxymel, one by the honey, and three by the collodio-albumen, or modification thereof.

It seems very singular that the process advertised, "which gives results equal to any wet, and superior to all other dry ones," should not have afforded one specimen; is it because they are too choice for common eyes to look upon? or is it because the parties recommending the process do not feel quite confidence enough to trust their specimens before the scrutinising eye of the public?

Hoping to see in the next Photographic Exhibition pictures printed by the silver process, from dry or keeping plates, equal to those printed by the carbon process (in the journals),—I am, yours, &c.,

AN ENQUIRER.

[A fair challenge, which we trust will be responded to. The writer of the preceding letter is a sceptic as regards the Fothergill process, when compared with a certain other dry one—in which he is a most skilful manipulator. We like to compare results, and think such a proceeding highly advantageous; but we have *no doubt* that the Fothergill process can yield negatives quite equal to any other. Indeed we are convinced that *all* the dry processes can be made to work satisfactorily.—Ed.]

ALABASTRINE PHOTOGRAPHS.

To the Editor.

Dear Sir,—My esteemed friend, Mr. G. W. Simpson, having sent me the enclosed note, in justice to myself and him permit me to ask the favour of its publication. With regard to the permanency of the pictures in question I must add that Mr. Simpson has shown me pictures in a perfect state of preservation which I remember to have seen at least two years ago. In referring to the bi-chloride of mercury process I still hold the opinion I have expressed; but, with regard to my friend's modification (both in tone and permanency), I must say, that results would seem to warrant a more favourable verdict.—I am, yours, &c.

90, *Cannon Street West, City.* ALFRED H. WALL.

My Dear Wall,—I have just seen your remarks, in answer to "Alabastrine," in the last number of The Photographic Journal, in which my name is mentioned in connection with the alabastrine process. Will you allow me to define my position in that matter.

The modification of the bi-chloride of mercury process, which gives a pure white tone instead of the cold blue effect produced by bi-chloride of mercury alone, and the materials for the production of which are sold by Squire and Co.,—this modification, together with the term which describes it, namely, the "Alabastrine Process," was really "invented" (shall I say) by me.

You have not heard me claim the "invention," because I have always shrunk from displaying the petty vanity I have often seen, and always deplored, of claiming the credit of "discovery" and "invention" for modifications, however valuable, of the discoveries of others. The process cost me some time and money in perfecting, and I derive some compensation from the sale of the preparations. With this I have been content.

In regard to the permanency of alabastrine pictures, I should, indeed, be a bold man to assert of any class of photographs that they would be permanent under all circumstances; but, I may state, that I have many alabastrine photographs in my possession which have been taken for betwixt two and three years that are in no degree changed. No process, imperfectly conducted, will give permanency; but I have reason to believe that the alabastrine process, *properly conducted*, will give as much certainty and permanency as any known photographic process—in fact all the permanency that can be desired.—I am, yours, &c.,

November 22, 1859. G. WHARTON SIMPSON.

BIS DAT QUI CITO DAT.

To the Editor.

Sir,—I was too far from the Secretary at the last meeting of the London Photographic Society to hear the whole of the letter suggesting that an annual subscription should be raised for the education and general maintenance of the children of the late Mr. Scott Archer; but the purport of the letter appeared to be that every photographer should subscribe one pound one shilling or ten shillings and sixpence annually, for eight or ten years. This proposition does the author of it very great credit, more especially as a sevenfold proportion will fall on his own shoulders; but it seems to me that it is open to several very serious objections. Every one who has been at all connected with charitable institutions will bear me out in saying that it is a most difficult and arduous task to maintain even the smallest annual subscription beyond two or three years. The amount of hunting up and worrying in such cases is almost incredible. The difficulties of collection, too, year after year, would be very great. The country-town photographers are very nomadic in their habits, generally wandering about from town to town. Even in our own city how many establishments have ceased to exist within the last few years!—how many have changed hands, and how many of our first-rate men have been taken away from amongst us by death! I fear much that after a couple of years the poor collector on going his rounds would find that Mr. A—— was out, and that B—— had sold his business to C——, who did not care to subscribe; that D—— had gone to South America to photograph the ruins of the City of Pococatepetl, and so on to Y——, who had gone on an African exploring expedition, and Z—— who had gone to America for the benefit of his health, having burnt his fingers in trying the ink process on paper embossed by Her Majesty's Stamp Office. Then again we are to have Louis Napoleon for our ruler next year or the year after, and he will to a certainty interdict the art of photography, as being much too truth-telling for his enlightened government. Who knows, either, whether the collodion process may not be shortly superseded by a new and more perfect process, as itself superseded the daguerreotype. Possibly a raspberry jam, lemonade, or milk-and-water process, as it is now the fashion to seek for new photographic materials in the kitchen instead of the laboratory, may be the grand photographic climax. But to speak seriously on this really serious subject, it is much more for past than for future benefits that we are in justice indebted to Mr. Scott Archer, and the plan of an annual subscription does not seem to me the way towards endeavouring to cancel the debt.

The proposal I have to make is this, that the various photographic houses in the United Kingdom should follow the example set by numberless city firms at the time of the Patriotic Fund and Indian Mutiny subscriptions, and set by one day's receipts. Let all their operators and assistants follow the example of the city clerks, and contribute one day's pay towards the fund. This being the worst time of the year, the day would have to be fixed some three or four months hence. In the mean time let the public know that the receipts of that particular day are set apart for a charitable purpose, and perhaps they who are so assiduous in dining, dancing, concert-frequenting, playing at shop in pleasant parks, and so on, for benevolent objects, will also have their portraits taken for charity's sake. Perhaps it will be objected that photographers will not like to have their daily receipts known to the public. Well and good—perhaps they may not; but that difficulty is easily obviated by the particular amounts being communicated to the Archer Fund Committee *only*, the secretary giving each firm a receipt for their contributions, simply publishing the names of the firms, and the total amount contributed. The tardy way in which the few hundreds already subscribed have been collected is a disgrace to the photographic profession. Let us all join heart, hand, and purse to wipe away this stain on our character.

The importance of the subject is too great to render it necessary for me to apologise for taking up so much of your valuable space.—I am, Sir, yours, &c. LONDON PHOTOGRAPHER.

[We had such a superabundance of matter already in type for the last number, when the preceding letter came to hand, that we were quite unable to find room for it then; but although it has already appeared in the pages of a contemporary, the spirit in which it is written is so good that we cannot do otherwise than insert it, with every wish that it may not return void.—Ed.]

ANSWERS TO CORRESPONDENTS.

A "Note" for America.—We have no objection to our American cousins copying our articles into their journals, if acknowledged; but when the Editor of the *American Journal of Photography* in the Number for the 1st Nov., extracted upwards of twelve of its pages (being within three-and-a-half pages of its whole number) from our columns, the least he ought to have done was to acknowledge the source whence he had borrowed nearly all his matter.

Charles.—Apply at Solomon's, Red Lion Square. (See Advertisements.)

Qui Fecit.—We never heard of the feat, and, what is more, we doubt the alleged fact.

Camera.—See our leader. If *you* like to try your hand upon taking negatives on cylindrical surfaces we have no objection, but don't ask us to do so.

S. Harewood.—Put the glasses into *warm* water first, and then into *hot* water, and you will find that you can get off the varnish by rubbing with a cloth.

T. Cowell.—See the report of the Caledonian Photographic Club. You will perceive that the lens actually tested was not constructed quite according to the formula given.

F. B.—You may well express astonishment at what we are reported in the Society's Journal to have said at the last meeting of the Photographic Society. We need scarcely refer you to our own columns for what we did say, but there are doubtless many who will give us credit (?) for it.

Subscriber.—1. We do not approve of the process you mention—all the good points are mere copies of others, and some objectionable ones are introduced. It is not nearly so simply as the "Fothergill" process or the metagelatine one, which it most resembles. 2. Acetic acid in *small quantity* tends to preserve the lights of albumenised paper when sensitised, and does not act objectionably to any extent. 3. Fused nitrate of silver, if *impure*, is apt to be worse than the crystalised. If pure, it is very good for baths.

J. B. B.—There is no *work* on the subject in existence. You most likely do not focus with sufficient accuracy. Ground glass is quite unfit for the purpose of a screen: use a collodionised-sensitised glass, well washed and dried, as a focussing screen. You require a microscope to focus with, and to know how to use it. Any good collodion will do with a pyrogallic developer. You will find the paper you require in the *Journal of the Photographic Society*, November 21st, 1857. You will find, also, many points noticed in reply to "Amateur" and "Querist" in some of our back numbers.

A Lucky One.—In adding carbonate of soda to your acid nitrate of silver bath, you should have *stirred well* between each addition before applying the test-paper. It is impossible that you could have *really* required three-quarters of an ounce of carbonate of soda to neutralise the acid in sixty ounces of bath—the proof of which you yourself afford when you state that a *flocculent precipitate* filled one-third of the jar. This was *carbonate of silver*, a portion of which was dissolved by the acetic acid subsequently added. The precipitate fully accounts for the great reduction in strength of your bath when afterwards tested. The "yellow frothy mess" should have been skimmed off. That is one of the advantages of treatment by carbonate of soda. The effervescence *throws up* much of the organic impurity contained in the old bath; but if you have thrown away your "flocculent precipitate" you have sacrificed the *best part* of your stock. This should have been washed with distilled water, and redissolved with pure *nitric acid*, to convert it into nitrate of silver.

Your present bath will very likely do for "Taupenot" plates, but we should not recommend it for the "Fothergill" process. It contains nitrate of soda, acetate of silver, and nitrate of silver, and is probably but very little acid if you have correctly described your treatment of it.

In Type—"Eusebius," "T. C. B."

Errata.—In our last number an error occurred in printing Mr. J. Heywood's paper *On Toning Positive Prints*. In formula No. 3, "pure water, 1 ounce," should be "pure water, 1 *drachm*."—In Mr. Ennel's paper, page 281, second column, lines 7th and 9th from top, the word "premise" should be "*premiss*."

THE PHOTOGRAPHIC JOURNAL.

No. 108, Vol. VI.—DECEMBER 15, 1859.

With the commencement of the volume which we now complete we assumed the modification of our former title under which we at present appear, in accordance with an announcement to that effect in the last number for the year 1858. Our readers will probably remember that the editor of the *Journal of the Photographic Society* paid us the compliment of supposing that our change of title would materially interfere with the prosperity of the Journal under his management; and upon the ground that the latter was familiarly known by the designation we had adopted, issued the succeeding and subsequent numbers of the Society's organ with the words "The Photographic Journal" prefixed to the then existing title. These proceedings naturally produced a collision between the proprietors of the respective publications, and an appeal to the law appeared almost inevitable; fortunately, however, the esteem and friendship existing between the two editors was not once interrupted, and they continued to regard each other with feelings of consideration and kindness. A proposal, emanating from the representatives of the Photographic Society, to refer the matter in dispute to arbitration was at once accepted by the proprietor of this Journal, and a written statement of the case, on both sides, was drawn up and laid, many months ago, before the gentleman chosen to mediate between them.

It is an anomaly, perhaps hitherto unprecedented, in the annals of periodical literature that two distinct publications should for the space of twelve months continue to appear under the same leading title; and though differing materially from one another, both in appearance and general characteristics, it was found that considerable inconvenience resulted occasionally to both from the close similarity of the title, principally when contributors to and correspondents with either journal made references to articles that had previously appeared in one or other of them.

It is, then, with much pleasure that we have to announce that a perfectly amicable arrangement has at length been concluded between the disputants, and for the future the Society's Journal will retain its present designation, while the title of this publication will once more, and we believe for the last time, undergo a slight modification, though its aspect, arrangement, and general appearance will remain entirely unchanged.

On the first of January next we purpose greeting all our old and, we trust, many new friends as THE JOURNAL OF PHOTOGRAPHY, which we hope will be found a *distinction* without a *difference* in more than one sense of the words employed. We have dealt thus far with the prospective, let us now turn a retrospective glance at the photographic acquisitions of the year just about to pass away.

At the commencement of the present year we realised the fact of our favourite science having taken such a firm hold on public estimation that its followers would be likely to increase daily in number, and with so many workers in the field it would become more than ever necessary that they should be supplied with accurate and reliable information of all that was going on around them in the photographic *world*. It was our ambition and aim, not only to meet this requirement, but also to offer suggestions relative to promising fields for research; to afford ready and willing assistance, by advice, to those seeking it; to criticise in an independent yet kindly spirit such works as might come under our observation; to comment on the proceedings of the various bodies ostensibly combined for the furtherance and elevation of our art; to notice such literary productions connected with photography as might appear; to draw attention to all unusual phenomena with which we might become acquainted; and generally to be ever on the alert to provide instruction and amusement for our readers. In how far we have been successful in our endeavours to perform these multifarious and sometimes onerous duties, it is for them, not us, to judge. We only know that our labours have been carried on in a sincere and conscientious spirit. If we have been called upon to censure, we have done it with regret; whilst commendation has been accorded probably with more pleasure to us than to its recipient. In the eagerness of controversy we may possibly have given expression to some unguarded word. If any such has inflicted a wound, we sincerely express our regret: we would that photography should be for all engaged in it a bond of amity, and not a source of discord.

When we began this volume we doubled the space which we had until then devoted to a record of the doings amongst our photographic brethren; but so energetic have they been that even this large increase has been frequently found totally inadequate to the purpose, and we have repeatedly had to meet the difficulty by affording more and still more space; and though it entails upon us much additional labour and expense, we hail it as a very encouraging sign of the active vitality of the photographic body.

To our numerous kind friends we have to return our best thanks for their active support in affording many valuable contributions to these pages—the liberality of some professional ones is in this respect deserving of especial recognition. We have many acts of courtesy to acknowledge; and, although it would be unreasonable to expect, holding as we do a somewhat necessarily conspicuous position, that we should entirely escape an occasional misunderstanding, we may consider ourself as unusually fortunate, for with one single exception, to which it is unnecessary more particularly to allude, we are not aware of having excited any malice.

Although during the past year no grand discovery has been made involving anything absolutely new in principle, we may safely affirm that we have made considerable advance in a better understanding of the laws influencing some of the established, well-known phenomena, especially in connexion with positive printing upon paper, and also with the numerous variations of the dry processes for taking negatives upon glass plates. With respect to the latter also we think enough has already been accomplished to afford a reasonable hope that we shall at no very distant day be enabled to prepare plates that shall be as sensitive as any of the most rapid of our wet processes. The elements of success are in existence, as witness what has been done by Mr. Kibble, of Glasgow, though at present we cannot certainly exactly say what has conduced thereto.

In negative processes upon paper a new vein has been struck

by Dr. Maddox, of Southampton, which bids fair to reward experimentalists in that direction.

Ink-printing, carbon-printing, and photo-lithography have each secured a very large share of attention during the past twelve months, while the Hon. H. Fox Talbot has been pursuing his researches with considerable success in photoglyphy. With ink-printing processes we have been disappointed; the results have by no means equalled the expectations in which we had indulged. Photo-lithography is not easily compassed by the majority of photographers, and when a fine impression is fortunately accomplished upon the stone, it requires a more than ordinarily delicate treatment to print off the copies. This is however a field in which much yet remains to be done.

Carbon-printing proper has not apparently advanced a single step since we last noticed it—if we except the productions of M. Joubert, which we had an opportunity of inspecting at the recent meeting of the Photographic Society; but unfortunately the process by which they are effected is still a secret, and likely to remain so. In the specimens which we inspected, those from photographic negatives of natural objects, statuary and landscapes presented a considerable amount of fine half-tone—the weak points here appearing to consist in high lights not quite uncontaminated, and in presenting a slightly grey and flat effect. These failings we regard, however, as much more likely to be overcome than the want of half-tone hitherto so marked in carbon prints.

In connexion with artistic photography proper, we may allude to the reproduction of works of art, which has been carried by Messrs. Thurston Thompson, Bingham, and Caldesi and Montecchi, to a pitch of perfection almost unhoped for; and in another direction the substitution of coloured photographs for ordinary miniatures has been carried to an enormous extent. This last-named proceeding has created a demand for instruction in the peculiar manipulations requisite in following out this operation, and we are happy in having been the medium through which the very best practical information has been supplied: we allude, of course, to the articles of Mr. A. H. Wall, still in course of publication.

There is one feature that we have to remark upon with the highest satisfaction: we allude to the marked and increasing excellence of the artistic element that has in certain quarters been infused into photographic productions. Here until lately was one of the weakest points of photography; but now we are in a fair way to wash out the reproach, and that without any sacrifice of truthfulness or minuteness of detail. Of this fact we have no doubt: the occasions when we have had to notice it have of late been more and more frequent.

Photography, in its application to scientific development, has been materially advanced: as one instance we may refer to Mr. De la Rue's paper upon astronomical photography, read at the recent meeting of the British Association, and recorded in these pages.

In the chemical department the principal novelty has been the introduction by Dr. Schweitzer of a new solvent of cellulose, called by him the oxide of cuprammonium, which it was hoped might advantageously replace the ordinary collodion when saturated with fine cotton or other kind of pure lignine. Hitherto this has not been found to be quite so convenient, though Mr. Heisch, of Blackheath, has shown that it is quite practicable to substitute it for ordinary collodion with equal results, but unfortunately entailing more trouble as at present prepared.

The science of optics as connected with our art has received an unusual degree of attention; but all the great improvements that have been effected were accomplished before the present year. We have however to rejoice in the fact that, the attention of operators having been thoroughly aroused to the importance of procuring as perfect an optical arrangement as possible, a stimulus will have been administered to the various makers of lenses to be more careful in future relative to the perfection of the instruments which they suffer to leave their hands; for when a good lens is not appreciated it is an inducement for the makers of lenses to be careless in their production.

Many improvements and conveniences have been suggested in the construction of various kinds of apparatus employed by the photographer, amongst which we may notice prominently the preservative box for sensitive paper, which appears to be perfectly efficacious.

Several of our friends have communicated accounts of their expeditions in search of the picturesque as food for the camera, and these have generally commanded a considerable amount of pleased attention from their readers, as affording a sort of photographic light reading contrasting well with the solid matter of more regular articles.

Several new Photographic Societies have been established in the provinces, and a fourth in the suburbs of London; thus affording still further evidence of progress in popularity.

We have in every number issued during the year 1859 been able, by aid of our Paris correspondent, to keep our readers *au courant* with photographic progress on the continent; while the occasional communications from correspondents in America, our own colonies, and other parts of the globe, have been sufficient to record anything of interest in the respective quarters whence received.

Notices of the various exhibitions held in this kingdom and also in Paris have, from time to time, appeared in our pages, not in the form of bare catalogues, but critical examinations; and reports of meetings, including not only the papers read at the numerous societies, but also the discussions to which they have given rise, when much valuable information has frequently been elicited.

We have had to deplore the loss of one eminent as holding a place in the first rank amongst opticians, Mr. Andrew Ross—a loss so recent that it must be fresh in the minds of our readers.

We have now briefly enumerated the occurrences of a photographic kind which have befallen us in 1859: we trust that the coming year may be rich in discoveries, and afford a large measure of satisfaction to our friends.

With our next number we shall present with each copy a **PHOTOGRAPHIC SHEET ALMANAC,** containing the days of meeting of all the established Photographic Societies in convenient form for reference by the members of each, together with sundry other useful matter.

In conclusion, we have only to state that no exertions on our part shall be wanting to make THE JOURNAL OF PHOTOGRAPHY even more useful and interesting than it has hitherto been in any phase of its existence; and wishing our readers all a happy Christmas, we pass to the other "orders of the day."

Our French knights of the camera do occasionally astonish us, in spite of our declared intention of not being astonished at anything. At the October meeting of the French Photographic Society the Duc de Luynes presented a considerable number of positive proofs "taken by a process which presents strong assurances of permanence, and which excludes the salts of silver." This gentleman it is who has already distributed a handsome premium to encourage operators to seek for a permanent method of printing, and who has offered a still more munificent prize for the more perfect attainment of the same end. The proofs presented were principally effected by means of the perchlorides of iron and gold; and, when at the close of the communication, Mr. Bingham remarked that these agents had already been employed by Sir John Herschell as the basis of a process named by him the *Chrysotype*, the President replied "that notwithstanding the labours of Sir John Herschell (!) the communication of the Duc de Luynes was *highly interesting*, for his researches had been undertaken with a special and novel (!) object, that of producing proofs as unalterable as possible." (!!!) Is not this a triumphant reply?

The Woodward camera is beginning to excite the maledictions of some of the Paris photographers, who, naturally enough, object to have an arrangement patented which they declare to have been used by them years ago. Amongst the malcontents we notice the names of MM. Chevalier, Jamin, and Bertsch — names not altogether unknown as connected with the optics of photography.

The subject of obtaining *direct transmitted positives* in the camera is engaging the attention of French photographers, and it is one that we regard as of special importance at the present moment, as intimately connected with that of producing *enlarged copies*. The reason is obvious. If we can effect by the camera the formation of a *transmitted* positive under the same conditions as those which now influence the production of a negative, instead of printing on *paper* by aid of the megascopic camera, we should be able to produce upon glass plates as many printing negatives of increased dimensions as may be desired. When done with, these need not be retained, for by keeping always the *original camera impression* we could at any time reproduce the printing negatives with but little trouble, and at the mere cost of chemicals employed. It would not only do away with the compulsory accumulation of large masses of glass, but would enable us to go into the field unencumbered with the heavy clog under which we now have to work.

The most promising scheme that has been suggested for producing these *direct positives* is one brought forward by M. Edmond Becquerel on behalf of M. Poitevin, which consists in an application to collodion of a process invented by our countryman, Professor Grove, for employment upon paper. We regret to notice that not one word seems to have been said relative to the origin of the *principle* employed, Mr. Grove's name not having been mentioned in any way. In a little pamphlet, entitled *Photogenic Manipulation*, by Mr. Robert J. Bingham, published in 1852, at page 68 we find the following:—

> At the second meeting, at York, of the British Association, Professor Grove described a process by which positive pictures could be taken at once, without the trouble of having to take a negative in the first instance. Ordinary calotype paper is darkened till it assumes a deep brown colour, almost amounting to black; it is then re-dipped in the ordinary solution of iodide of potassium, and dried. When required for use it is drawn over dilute nitric acid, one part acid and two-and-a-half parts water. In this state those parts exposed to light are rapidly bleached, while the parts not exposed remain unchanged. It is fixed by washing in water, and subsequently in hyposulphite of soda or bromide of potassium.

To M. Poitevin's application of this principle we see no objection; but we should have been better pleased had we found some recognition of Mr. Grove as the *originator* of it. The process is not only interesting but likely to be highly useful: we therefore give it as follows: —

> To obtain direct proofs by transferring I employ a collodion iodised with potassium salt, but containing less of it than is usually added for a negative collodion. I sensitise as usual, and expose the film for a few seconds to direct light. Its appearance is not changed. I wash plentifully, and dry for future use, or else continue the preparation at once. I cover the moist surface that has been exposed to the light with a solution of twenty grains of iodide of potassium in one ounce of water, the operation being performed in the dark room. When the film has been dried, instead of a solution of the iodide in *water* I use one of the same strength in alcohol. The film may be exposed an hour or two after preparation, if preferable to keep it so long. The exposure required is about three times as long as that for an ordinary negative with the same collodion. After exposure, the film is washed with distilled water to remove the excess of iodide of potassium, and I then plunge it into a weak bath of nitrate of silver, and develope with acidulated pyrogallic acid, *which darkens the parts that have* NOT *received the action of the light.*

We trust that some of our energetic readers will work in this direction.

We have to remind our friends that all works intended for exhibition at the forthcoming seventh annual display under the auspices of the Photographic Society should be addressed to the Secretary of the Society, and delivered, with all expenses paid, at the Gallery, No. 5, Pall Mall East, on the 27th inst. It is in contemplation to open the Gallery to the public, as usual, early in January next. Want of space precludes our giving the regulations in detail; but, as they are identical with those issued last year, the omission is unimportant.

THE PHOTOGRAPHER'S VISION.
A FAIRY TALE.

By One Who is Now "Thoroughly Wide Awake."

With the laudable determination of becoming an out-and-out photographer in the coming season, I lately commenced a study of the required outfit. For several evenings I read of nothing but cameras and lenses, and had just arrived at the conclusion neither to purchase a camera so small as could be carried in the waistcoat pocket, nor so large as to require a two-horse power van, when, tired out by so arduous an investigation, I dropt asleep and presently dreamed, and my dream on this occasion, while very natural (as you will admit) under the circumstances, was also so peculiar that I thought it worth recording.

My first perception in the dream was, that of being transported by rail, some one hundred miles, at a fabulous rate, holding on by a magnetic wire: next, that of being conveyed in a cab to a strange house, and snugly ensconced in an arm chair in a strange room, in which, after rubbing my eyes, I perceived that a number of strange little beings were already located, some lying on chairs, some on tables, and others bolt upright in cases in which they had recently arrived, carefully enveloped in French wadding.

These little creatures or fairies, as they appeared in my dream, were of various forms and sizes, but had one thing in common — they all wore hoops — no whalebone or muslin affairs — but good stout brazen ones. Finding myself unnoticed, I concluded that I must be invisible, and ventured to quietly survey the novel gathering of sprites while listening to their prattle.

Most of these little beings had evidently come a considerable distance, and a general feeling of disappointment pervaded the whole company. Each one, before leaving home, had somehow been given to understand, that whatever good qualities she brought with her the same would be recognised and acknowledged at this the appointed place of rendezvous; but how these fond hopes had been dashed, did not for some time appear.

"I tell you ladies," said one of the smallest of the party, "that we have all — I mean all that are at present in this room — been *bamboozled*. Did we not all come here understanding that we were to be judged by our good qualities and merits generally?" A general cry of "Yes!" "Did any of you receive intimation that your good qualities, no matter how precious, would be passed by unnoticed, except you also possessed some one quality in absolute perfection?" An indignant "No!" from all the fairies. "For my part," continued the little fairy, "I came here quite confident of success; for although I have by no means the *quickness* of some of my more bulky sisters, yet I have equal *sharpness* with the best of them, and I fancy that when properly treated — I mean when I am allowed to look straight forward instead of being obliged to stare upwards, as some of our patrons occasionally insist upon — that I am as free as need be from dis—" Here the fairy instead of finishing the word twisted her little mouth, and all the other fairies nodded their heads in token of comprehension.

Another fairy remarked, though she guessed soon after her arrival how it would be — "When I saw," said she, "the carelessness with which I was examined for all but one quality, and that I was laid aside the moment it was ascertained that I did not possess that quality *in perfection*, I perceived that it was just like throwing pearls before swine to have exposed my perfections to the scrutiny."

The immediate cause of disatisfaction was now in some measure made apparent by an elder fairy, who spoke in rather a majestic tone: "Sisters," said she, "we are all by this time confident that the award of merit is already conferred upon our relative so long closeted in the adjoining room. We are all equally confident that this award is contrary to all decency and propriety, but 'man was ever a deceiver,' and in the present instance he has induced us to leave our comfortable homes under pretences and assurances which he now repudiates. But, my sisters, you are not as well aware as I am of how this has happened. You know that I am gifted with second sight, and I now tell you that a fair trial was intended you, and might have taken place but for a confounded" [I thought this rather an unsuitable word for a fairy to use] "and undue in—" Here a door suddenly opened, and a porter appeared bearing a case, in which was seated *the favourite* fairy of the next room. The

porter having deposited her on the nearest table looked rather timidly at the rest of the company and said — "Ladies, she's got the prize after all." "After all *what* pray?" said an elderly fairy sharply. The porter seemed taken aback and hesitated. The fairy repeated her question with a trebled sharpness. The porter looked despairingly. "Well then, miss," said he, "If you must know, I mean, after all the pains which have been taken in the next room to lessen her imperfections, and she's no better after all." On this the fairies put it to the vote, and carried it unanimously, that the porter was an honest fellow.

Just at this moment the room was darkened by something passing the window on the outside, and a junior fairy exclaimed, "did you ever see such a *pen* as that figure is carrying?" "Its a club," said another. "No," said a third, "its a pen, and nearly all feathers." Instantly there was a clatter of fairy tongues, one half asserting it was a pen, the other that it was a club. When this had subsided, the favourite fairy, who I had perceived to be much elated as the figure had passed, spoke in a contemptuous tone as follows: — "I can set the question at rest, my poor relatives; it is both a pen and a club. The fact is, it was once only a pen, and father a clumsy one too; it had got much the worse for wear, and had, besides, suffered somewhat in my defence, so, in charity, I contrived that it could be used indifferently as a club or a pen. A formidable weapon it now is I assure you, able to crush one of you at a blow, or to prove black to be white, or white black, *by an instantaneous process*.

I thought that some of the fairies turned pale at this speech, but one of the bolder ones asked the favourite whether her present elevation was "due to the pen-end or club-end of the weapon."

What the result of such a ticklish question might have been it is impossible to divine, as a loud ring of the bell startled both the fairies and hurried the porter to the inner room. Seeing that in his hurry he left the door open I ventured to follow, and found myself (in my dream) in company with several gentlemen. It was evidently the remains of a broken-up conference, with the addition of a visitor who had dropped in to gossip.

Perceiving that I was equally invisible in this room as in the outer one, I ventured to take a vacant chair and make my observations at leisure.

One gentleman was still seated at the table, two others were half-turned aside, making the most of the light at their command (this not being over good) while examining some papers. Each of these gentlemen had a small medal attached to a button hole, with the letters M. L. C. in bold relief. The visitor had no such insignia of office. At the further end of the room was a second door apparently leading into a smaller room or closet.

While I was busied in making these observations, the M. L. C. at the table had instructed the porter to have the favourite in readiness when called for. The porter had retired, shutting the door, and the conversation was resumed.

"Well!" said the visitor, who had seated himself opposite the first M. L. C., "what can I say in defence of the M. L. C. for uttering such a verdict." "Now, don't be too hard upon us, my dear sir," replied the other, "we have had, I assure you, great difficulties to contend with. Those little creatures in the next room, fairies as we call them, are so *peppery* that really we feared the consequences of saying too much about them. They might have kicked up a row and scratched each other's faces; what a sad plight that would have been to have sent them home to their friends in."

"Umph," said the visitor, "did not you know of their 'peppery' qualities before you brought them together?"

"To be sure we did."

"Well then, could you have taken a surer way to get up a *fracas* than huddling them together as you have? You must recollect that your brothers in the South were thinking of making just such a gathering, and got so frightened at the probable consequences that they gave it up." "That's all very true," replied the M. L. C., "but we thought that by selecting just one quality, or perfection, and trying the creatures upon that and that only, we might escape the difficulty."

"Umph — escape one difficulty and tumble into a greater, or, as the old saw, 'out of the frying-pan into the fire;' but this reminds me to ask a question: when was that course of procedure adopted?"

No immediate answer followed. After a short pause the visitor said, "*Before or after* you invited the fairies to congregate here?" M. L. C. (after a short pause), "After."

"Well," said the visitor, "I shall not attempt to inquire how far such a course was *considerate;* but may I ask who suggested it — one of you M. L. C.'s or some party exterior to the Committee?"

The one M. L. C. looked at the other two M. L. C.s, and significant glances passed between them; at length the first M. L. C. slowly said, "I am inclined to opine that that must be considered as a Committee secret."

"Oh very well, my dear sir, pray don't tell me anything I should not hear. The object of the formation of the committee I apprehend was to afford better information, respecting the merits and capabilities of the fairies, to those requiring them in practising their black art."

"Certainly," said the M. L. C.

"Then you were essentially a Committee of the practicers of the black art, and as such were expected by them to forward their interests."

"Just so."

"And *not* a Committee appointed by the fairies for blinking the other party."

"Certainly not."

"Then why aid and abet the machinations of even your favourite fairy for blinking your brothers in the black art by stating her perfections only, and keeping out of view her opposite qualities?"

"We did not wish that our brothers should be blinked; but we wished to keep out of scrapes. Now, then, you have the whole secret of the matter."

"You did not choose to get into a scrape with your adopted one, but preferred rather to do so with the host of the rejected. Umph! there must be something very interesting or very peculiar about your favourite. I hope her *symmetry* has not blinded you." [Visitor here looked at his watch.] My time is come, I find, for a call; but I shall return in half-an-hour, and hope then to be favoured with a peep at her *ladyship*." So saying the visitor vanished, and the porter appeared with two letters, which he handed, one to each of the M. L. C.s, who had as yet taken no part in the conversation.

"James," said the first M. L. C. to the porter, "has that door between this room and the closet been properly secured? You know that we desired there should be no further communication through it."

"Yes, sir," replied James, "and a difficult job I had of it. The lock is half spoiled, sir, by some old pens being poked into it. Did you ever, sir — [James here looked a little mysterious] — hear any strange noises coming from that closet?"

"You are superstitious, James, I do believe — get away."

James, on this rebuff, retired, muttering that "since the fairies had come to the house there was no peace for him at least."

I perceived that the other two M. L. C.s had by this time read their respective letters, and now each read his letter aloud — *pro bono committico*. The first ran as follows: —

DEAR SIR,

Understanding that you are an active M. L. C., I hasten to address you on a matter of some importance. From the high opinion which your Committee has favoured the public with in reference to your *favourite*, I instantly set about making one — two of the now antiquated beings yclept "landscapes," precisely similar ones, belonging to a friend, the other my own, and one of my poor spectacle eyes, which happened to be a concave of just the required focus, were sent to a first-rate hand, with all sufficient instructions. The affair — I mean your favourite — was received enveloped in a good smart bill, in which the job was termed special and very troublesome, and looked as handsome as you could wish, and quite symmetric; but, lo! when we tried it, although it gave, as stated, no distorsion, yet in other respects one of the unfortunate old *landscapes* which had gone to its construction would have been far preferable. When you write me, dear sir, as I am sure you will, stating how the L. M. C.s got so good results from their favourite, perhaps you will also inform me how two lenses which have their *foci* coincident, combined with one which has not, can form a combination which *has*. I should have thought this could not be, if I thought at all about it; but in my hurry to get hold of the *acme of perfection*, I thought of nothing but its possession.

Most truly yours, dear sir,

* * * * * * * *

P.S. If the Committee should have made a mistake, I hope they will think it fair only to reimburse me out of their stock-purse the expense I have been uselessly put to in consequence.

The second letter was now read: it began with —

MY DEAR M. L. C.,

I feel it my duty to give you the most timely information of what has just happened to me. Determined not to be behind hand in the possession of one of your favourites, I commissioned a friend in town to procure me one. Well, what do you think he has done? Why, he has sent me what is no more like it than "chalk is like cheese." It has no symmetry at all: not the slightest pretension to it. It is, in fact, the old portrait affair, a little altered and nothing improved, with a diaphragm in front, and includes just one-half the extent of view which I had expected. So I sent it back to my friend, telling him not to be *fooling me*, and to send me the proper thing. You will certainly not believe me when I tell you the result; but, 'pon my honour, he has written back telling me that *I* am "the fool for not knowing that it was all right." Now, is not this too bad?

Your affectionate kinsman,

* * * * * * * *

"A very pretty kettle o' fish I fear we have cooked," said the last reader. Some conversation in an under-tone followed, of which I could catch little except something about making "a clean breast of the matter;" but while straining my ears to catch the conversation, I heard distinctly a *scratching noise* coming from the direction of the closet. This had ceased, and the M. L. C.s were still pondering over the letters, when the porter again entered with another letter.

"More correspondence," said the chief M. L. C., "and not coming from far, for the cement is still wet—short and *apropos*, gentlemen, you will perceive as I read it :"—

Gentlemen M. L. C.s,

Don't be at all "fashed" if people choose to think or say that the symmetric fairy and your favourite are not the same. Leave it to me to convince them, if necessary, and I'll soon do it. It is done in one line—thus: "The symmetric fairy is *mine*; very well. Your favourite is *mine*; also well. "Mine" and "mine" are the same; then so are the rest."

Yours in haste,

A. B—— W.

P.S.—You see from my signature that I am, thanks partly to you, all but Alpha and Omega.

Any comments which might have been made on this note were prevented by the re-appearance of the visitor, escorted by the porter, who, anticipating the call for the favourite, had brought her in her box and deposited her on the table.

The visitor having made his bow took his seat close by, and having surveyed the fairy so far as her present situation in her case permitted, without touching her, said:—"Gentlemen, am I to understand that there is no mistake here."

"It's all right," said the porter, who had not left the room. The fairy was now passed round the table to each M. L. C. in succession, who confirmed the porter's statement.

The visitor now resumed his examination. Lifting the favourite clean out of her case, using both hands, and leaning his elbows on the table, he turned her over and over, attentively examined each end in succession—next unscrewed her, then put her all to rights again, and finally laid her on the table.

There was a short silence—broken by a loud

"Humph, Gentlemen, you have not called this fairy by her right name."

"We differ with you," said an M. L. C.; "we indeed acknowledge a slight alteration in her constitution since she was first described in print, but we are not fastidious, neither should you be."

"Neither shall I be," replied the visitor; "but come, we will appeal to the fairy herself. I know that she will speak the truth." "Come my little dear" (continued he), addressing himself to the fairy, "I shall ask you a few questions, and mind how you answer them. Do you recollect what you were at first?"

Fairy—"Oh, sir, I am so altered that I don't know whether I am myself or not."

Visitor—"Well, never mind that, but tell me what you once were—although you may be quite another now."

Fairy—"Sir, I was symmetry itself."

Visitor—"A fair outside perhaps."

Fairy—"Both outside and inside, I assure you, sir. You might have compared me to an hour glass—my head and my feet perfectly alike—my waist the envy of all my relatives—why sir, my master not only boasted of my fair proportions but declared that on them depended my good qualities. It was wonderful what I could do sir—with my waist tightened until I only measured one quarter of an inch across, I could pirouette over an angle of sixty degrees, but when my waist was reduced to one-half this I could actually cover eighty degrees—a most unheard-of feat I assure you, sir, at that time."

Visitor—"Did you ever try the latter feat?"

Fairy—"I can't recollect, sir, but I'm sure of this that it only remained to reduce my waist *to nothing* and I could have spanned the whole circle."

Visitor—"Indeed! Well, can you now say how you were brought to your present condition?"

Fairy—"Ah! no, sir. They must have given me chloroform, for I was unconscious during the operation. But, alas, I'm no longer the same—my head and feet are now quite different. I have no more symmetry than the most vulgar of my acquaintance. My beautiful waist is gone for ever [here the fairy dropt a tear]. My stays (or stops as they call them) are strangely enough *removed to my head*, and in consequence my view no longer extends beyond that of my sisters. But, what vexes me most of all, sir, is, that by these alterations I actually have lost my character of a *rara avis*, and have become a twin sister of the antiquated lady who has for so many years been taking portraits."

Visitor—"Your case is indeed a hard one, but can you say why you were thus changed."

Fairy—"I suppose I had some imperfections, and I believe I have them still. I was always blamed for being very slow and inclined to *mist*ification. They call it fogging, sir, but I don't think the word genteel."

The Visitor now addressed the M. L. C.s as follows:—"Gentlemen, the fairy has spoken the truth—she is, as she stands, no more a symmetric triplet *than my body*, or than either the portrait or Petzval ladies, both of which I presume you are familiar with—nay she is almost identical with the former. Doubtless, gentlemen, you will immediately publish an accurate description of both the construction and demerits of your favourite, so that your brother practitioners of the black art may be no longer liable to be led astray. Before I retire, gentlemen, allow me to put one more question to your favourite."

Turning to the fairy, the Visitor asked—"Pray my dear, why came you here under a wrong name?"

The fairy looked disconcerted and said—"Oh! sir, I had rather leave that question to be answered by the great pen."

Visitor—"What!—Penn, the famous Quaker! why child he's been dead and buried many years since."

"Oh! no, sir, not him, but a greater pen than him, at least in his own opinion."

"James," said the chief M. L. C., "What is that uproar in the outer room?"

"I declare, sir," said James, "the fairies are all getting into their cases and escaping!"

At this moment, the room appeared to darken. It was no longer day-light—candles burned and burned blue. The door leading into the closet partly opened and a tremendous pen—fully six feet high—at least it appeared so to me—stalked out. I imagined that, in the confusion which ensued, M. L. C.s visitor, the porter, and myself escaped into the outer room, from which by a desperate effort, and incurring sundry knocks on the shins, I escaped into the street. Here I awoke, and found the damage to my shins to be real, having in my dream kicked the poker and tongs about my room and the shovel under the grate!

ON THE FOCUS OF LENSES.

RESEARCHES OF M. CLAUDET.

[Read at the Manchester Photographic Society, December 7, 1859.]

It may appear a somewhat startling assertion to make, that there are comparatively few photographers who know much about the *foci* of the lenses of which they are constantly making use; yet such is unquestionably the fact. I do not mean, of course, to charge them with any incapacity for correctly "focussing," but with a general want of knowledge of the *focal lengths* of the various lenses which come under their notice, and more especially as regards portrait combinations which, as a rule, are reckoned as much shorter than they really are. This may seem a matter of but small importance, and yet there is more dependent upon it than would at first sight appear.

More than usual attention has been directed of late towards the various kinds of photographic lenses now in the market; and an attempt has been made (a somewhat lame one, it is true) by one of the photographic societies of some note to procure a semi-authoritative "report" upon the relative qualities of each sort, by constituting a committee of examination. As I have already remarked upon the shortcomings of the said "report" elsewhere, it is needless for me here to repeat the same; but my object in adverting to it is, to point out that one *essential* element of comparison consists in an accurate knowledge of the length of the *principal focus* of each lens examined, and I shall presently proceed to show how this may be readily ascertained.

Dependent upon this, also, is another matter that has of late attracted much consideration—I mean the enlargement of positive proofs from small negatives, as by a knowledge of the *solar focus* of a lens we are enabled to calculate to a nicety the exact distances between the negative, lens, and sensitive medium, in order to arrive at any required degree of enlargement. For an extremely ready method of making this calculation we are indebted to the researches of a gentleman who has before contributed many useful contrivances for the benefit of his photographic brethren—I mean M. Claudet, who, at the recent meeting of the British Association for the Advancement of Science at Aberdeen, read a paper on the subject; but in consequence of its having been written in the French language, and not yet published, I have been unable hitherto to procure particulars. A very short statement of the principal point of the communication was, however, inserted recently in a French periodical publication, edited by the Abbé Moigno (who himself was present at the meeting), and which has been quite sufficient to enable me to examine the question and verify the fact stated; at the same time, I have been so impressed with the great convenience of the method

that has been discovered by M. Claudet, of calculating the respective distances of the conjugate foci for any given lens together with certain other points of utility that have occurred to me during the examination, that I have determined to make a communication on the subject, as it is very uncertain how long it may be before photographers are in possession of M. Claudet's own paper. I would premise, however, that although M. Claudet may justly claim what merit there may be in this paper, he is not responsible for any misstatements or errors that it may contain.

So far as I have been able to ascertain it, the special point of M. Claudet's recent communication has been the discovery of the fact — "*That if the principal or solar focus of a lens be regarded as the unit of measure, an object situated in front of the lens at a distance from a certain point, equivalent to any* MULTIPLE *of the said unit, will have its conjugate posterior focus at a distance from another certain point equal to a corresponding* FRACTION *of the same unit.*"

This will, perhaps, be more readily understood if I put the proposition in a popular form, as follows: — Suppose we have a lens of *twelve inches* solar focus, — an object situated at *six feet* distance from a certain point in front of the lens, that is at six times the unit of measure, — the conjugate posterior focus will be at a distance of *one-sixth part* of the same unit — that is, at *two inches* distant from a corresponding point behind the lens.

So far as I am aware, this simple relation between the conjugate foci of lenses has been first observed by M. Claudet; for though we certainly have been able to calculate the respective distances from the lens of the conjugate foci, in any given case, it has been by a much more complicated method. Sir David Brewster gives the following rule, viz. — "Multiply twice the product of the radii of the two surfaces of the lens by the distance of the radiant point from the centre of the lens, for a dividend. Multiply the sum of the two radii by the same distance, and from this product subtract twice the product of the radii for a divisor. Divide the above dividend by the divisor, and the quotient will be the focal distance required." Now, besides the number of figures involved, this rule is of no use as regards a compound lens, the parts of which are separated as in a photographic portrait combination.

The proposition stated above (which is in italic) is all that the very meagre account given of M. Claudet's paper enabled me to gather, with the exception that the *certain points* named are situated the one before and the other behind the lens. The exact points I set about ascertaining, and, in order to do so, made the following reflections: —

In order to avoid the risk of misapprehension as much as possible I may, first of all, remark that all photographers are aware that the nearer an object is situated, with respect to a lens, the further from it, on the other side, must the ground glass screen be placed, and *vice versâ*. The object and the glass screen are, in either case, situated respectively in the *conjugate foci* of the lens.

To ascertain the limits within which the *back focus* of a lens is confined, we have only to remember that it must be between the points of the solar focus (that is, the focus for parallel rays) and the point at which the image is equal in size to the object. Now, it is well known that when the image is of the same size as the object itself, the two must be equidistant from the *optical centre* of the lens, and *each* twice the length of the principal focus from the same centre. It is therefore clear that, if in all cases where the object in front is at a distance that is any *multiple* of the solar focus, the posterior focus must be a *fraction* of the same, M. Claudet's *certain point* behind the lens must be that point located at the solar focus from the optical centre; and, further, that M. Claudet's *certain point* in front of the combination must also be a point at a distance equal to the solar focus from the optical centre; because when the image and object are equal in size, by M. Claudet's formula —

$$\text{The focus} + 1 = \frac{\text{The focus}}{1}$$

when measured from his *certain point*. The next thing to find was the *optical centre* of a portrait or other combination, and its solar focus. The former I ascertained in the following manner, as being simple and easily performed, though there are other modes of effecting the same object: —

TO ASCERTAIN THE OPTICAL CENTRE OF A PORTRAIT COMBINATION.

Arrange your lens as if about to take a portrait, and place on a screen any convenient object — a sheet of printed paper answers very well — then focus so as to have the sharpest possible definition upon the ground-glass. Measure the distance between the ground-glass and the *back* combination very accurately.

Be very careful to keep the object and ground glass screen *fixed* until after the next operation.

Now *reverse the lens*, and with the object and focussing screen still at the same distance apart, again focus carefully, and measure accurately as before the distance between the ground glass screen and the *same* part of the lens, which, in its last position, will be at a greater distance than formerly. Deduct the smaller length from the greater and *halve the difference*. The result measured from the back lens towards the anterior part will show the *optical centre*, and this point should be marked on the tube of the lens.

To verify the result obtained, proceed as before, measuring the various distances from the *front* part of the combination, halving the differences as before and setting off this distance from the front towards the back of the lens.

It is at the point ascertained as above where the diaphragms ought to be placed.

In a portrait combination the *optical centre* will be found to lie at a point between the components; in the best constructed ones, rather nearer to the front than the back.

In the orthographic form of lens, some point within the convex lens of the combination will be the *optical centre*.

TO ASCERTAIN THE PRINCIPAL FOCUS OF A PORTRAIT COMBINATION.

The principal or solar focus of a lens or combination of lenses is the focus for parallel rays measured from the optical centre. One of the simplest means of finding it is to focus upon any suitable screen a sharp image of the sun, and having previously ascertained the optical centre, measure the distance of the sharply defined solar image from this centre, as indicated on the tube. It is a good plan to mark this distance on the lens tube beside the line indicating the centre.

But if the sun be not available, proceed as follows: —

Select as distant an object as you can readily find, and having focused it carefully, you will know that the distance between the ground-glass and the "centre" mark on your lens will be a *trifle longer* than the solar focus. Now put up any regularly divided object (a sheet of ruled paper, or a foot rule for instance) at *double* the ascertained focal distance from your lens' "centre," and focus carefully. If the operation has been correctly performed you will find the image a trifle *smaller* than the object.

Move the object a shade nearer to the lens and again focus and measure accurately the size of the image, and continue thus until your image and object exactly correspond in dimensions; you have then nothing to do but to halve the focus so found to know the solar focus, of course always measuring from the *optical centre* of the lens.

As regards the application of the preceding, when comparing lenses one with another, a knowledge of the respective foci is indispensable, in order to allow of the observed results being of any value. Again by a knowledge of the very simple law of the relation of the conjugate foci, it is very possible to compare lenses of *different foci* one with another, making the requisite allowances before performing the manipulations of comparison, and yet obtain reliable results.

And thirdly, when using lenses to enlarge a negative, we may at once place the negative, lens, and sensitive surface, correctly in place, without any necessity for ascertaining by inspection whether they are in proper focus; a matter not only of great convenience, but absolutely admitting of greater accuracy than is readily attained by the ordinary method of focussing, when the lens and the image are necessarily at a considerable distance from each other.

I must crave the indulgence of my audience for the somewhat technical nature of this communication, trusting that the knowledge of the simple law of relation between the conjugate foci of a lens, as discovered by M. Claudet, may be found of sufficient interest and utility to excuse me for trespassing upon your attention.

GEORGE SHADBOLT.

THE POSITIVE COLLODION PROCESS, WITH SOME REMARKS ON THE ALABASTRINE PROCESS.

By G. WHARTON SIMPSON.

[Read at the North London Photographic Association, November 30, 1859.]

IT is a somewhat singular fact, that whilst the positive collodion process is regarded as the simplest and most easily managed of all photographic processes, there are found amongst exhibited collodion

positives a greater number of thoroughly bad pictures — productions at once a disgrace to photography and a burlesque upon art — than are produced by any other process. Perhaps, indeed, the very simplicity of the process, the ease with which *something* having a relation, however remote, to pictorial art, may be produced, is really the cause of this prolific spread of such photographic enormities. Certain it is that there are no mysteries in the process, no difficulties in the manipulation, to hinder persons of average capacity and ordinary care and perseverance from producing, under anything like fair circumstances, excellent photographic, if not always artistic, results.

In the details I am about to give of my own practice, I shall, at the risk of producing something very like an elementary treatise on the subject, begin at the beginning, and very briefly describe the manipulations in their natural order.

SELECTING AND CLEANING THE GLASSES.

The glass I prefer for the purpose is the best flatted crown, picked free from blemishes and scratches. The smoothest side should, of course, be chosen for the picture; and if, as is sometimes the case in large plates, there be a slight curvature, I coat the plate on the concave side. In regard to methods of cleansing, it is possible to obtain a perfectly clean plate — the thing imperatively required — by almost any of the plans recommended by various operators. The most certain and speedy method I know is by the use of a preparation sold for the purpose under the name of the "Photographer's Detergent." This is a liquid about the thickness of cream, which is applied to the plate with a piece of woollen rag, and which begins to dry almost immediately it is applied. It is removed by rubbing the plate with a clean linen cloth, all dirt and grease disappearing at the same time. A solution of somewhat similar character, perhaps not quite so good, is made as follows :—

Water	1 ounce.
Alcohol	1 „
Nitric acid	1 drachm.
Fine Tripoli *quantum suff.*	

The solution should be of the consistency of thick cream. A good method of applying it is with a rubber, made of a strip of list or woollen cloth, a foot or two long and three inches broad, rolled up tightly and tied with string. The advantage of this method of cleaning, either using the preparation just described or the "Photographer's Detergent," is that no water is required, and thus a considerable amount of time and trouble are saved; whilst the use of an alkali, always dangerous and of doubtful efficacy, is avoided. The cloths I prefer for the purpose are those of a strong coarse linen, known amongst housekeepers as glass cloths. Partially-worn diaper, which has been often recommended on account of its softness, is objectionable, as causing a large amount of "flue," the particles of which cling about the glasses. The cloths should be frequently washed in boiling water without the use of soap. The wash-leather for giving the final polish I generally treat when new in the way I formerly practised for cleansing the buckskin used for covering the buffs for polishing Daguerreotype plates; namely, after beating them well, I wash them well in a mixture of equal parts of spirits of wine and water. In using the leather, I adopt the precaution of keeping one side — the rough side — always to come next the hand; and the other — the smooth side — always next the glass. By this means any chance of perspiration from the hand coming in contact with the glass is avoided. In some states of the atmosphere, and with some qualities of glass, every possible precaution is required to get a clean plate. If the plate cannot be got to appear satisfactorily clean, on breathing on it, it is best to throw it aside; as a good positive cannot be produced on an imperfectly cleaned plate.

THE COLLODION.

A variety of collodions essentially differing in characteristics have been prepared for the positive process by manufacturers, and a variety of opinions have been expressed as to the requisite qualities of a positive collodion — many recommending a thin lightly iodised collodion, and a weak nitrate bath, others enforcing the importance of a highly iodised collodion of good body, and a strong nitrate bath; some recommending the use of bromides and chlorides, and some preferring the simple iodide. Perhaps the diversity of opinion arises to some extent from different ideas being held as to what constitutes a good positive. Some authorities, of high repute, speak of the necessity of a very thin white deposit of silver, pure in colour, but without intensity. My own experience is decidedly opposed to this idea: such pictures, especially if backed with black varnish, generally appear comparatively poor and flat, deficient in vigour and perfectness of modelling. A collodion giving a rich creamy film in the nitrate bath, yielding on development a fair amount of intensity combined with pure colour, gives by far the boldest and most vigorous picture.

I have tried several methods of making soluble cotton for a positive collodion. The last formula given by Mr. Hardwich, in which a large excess of sulphuric acid is used, for the ostensible purpose of parchmentising the cotton prior to its conversion into pyroxyline, I have found to give an excellent cotton when it gives any at all; but on comparing my own experience with that of several friends who have tried the same formula, I find that a large per centage of failures has been the result. This has arisen, doubtless, from some slight unobserved or unknown error in proportions or manipulations; but the great danger exists, of which Mr. Hardwich himself speaks, of the whole of the cotton being entirely dissolved by the acids. The formula I have found to give uniform success both in my own hands and that of others is one, an approximation to which is, I believe, commonly used, but which I find given definitely by Mr. Sutton, and is as follows: — Of sulphuric acid s.g. 1.840 — the oil of vitriol of commerce is, I believe, sufficiently near the mark — and of nitric acid s.g. 1.420, equal parts by measure. To three measured ounces of the mixed acids, one drachm of cotton wool will be about the right quantity. The time of immersion not less than five minutes; the temperature being maintained at about 150°. I have found that the nitric acid most commonly sold, commercially, as pure nitric acid, has generally a s.g. of 1.360; and in this case I have found that six measured parts of sulphuric acid to four of nitric acid of this strength give an excellent soluble cotton. In either case the cotton gains fully fifty per cent. in weight, and yields an even sensitive film, adhering well to the glass and quite transparent in the shadows.

Six grains of either of these cottons will dissolve perfectly, with scarcely a perceptible residue, in equal parts of washed ether s.g. 750 and alcohol s.g. 820. More cotton would dissolve, but this is sufficient. Alcohol and ether of these strengths are easily procurable; and I have found after long use that the alcohol may be used, safely and with advantage, in at least equal proportions with the ether.

I may here state an interesting experiment I recently made with reference to the principle of alcoholic collodion, as proposed by Mr. Sutton, of Jersey. In order carefully to test the principle, we prepared in Mr. Sutton's laboratory, three samples of collodion. The first sample contained four parts of absolute alcohol to one of absolute ether, and constituted what Mr. Sutton has called alcoholic collodion. The second contained equal parts of the same solvents. The third sample contained seven parts of the ether to one of the alcohol. The s.g. of the ether was 723, that of the alcohol 799, and both were methylated. Each sample contained eight grains of cotton to the ounce, which dissolved perfectly. Each was iodised with iodide of potassium, fourteen grains of which were dissolved in one ounce of alcohol s.g. 820, of which solution one part was added to three of plain collodion. On adding the iodiser, in each case entirely different results were produced as to colour: the alcholic collodion took a pale straw or lemon colour, which it has preserved to this day — between two and three months — without getting deeper. The second, or half and half, rapidly took a pale sherry colour; and the third, or ethereal, became red within an hour. I may add, to explain the rapidity of these changes, that the cotton was slightly acid from hasty and imperfect washing. I brought these three samples to London, and tried them carefully against each other about a fortnight after they were made. The results were interesting and instructive. The first, or alcoholic, which flowed over the plate like oil, without the slightest trace of structure, required ten seconds exposure in a somewhat dull light to obtain a good picture; the second required fifteen seconds to produce similar results; and the third twenty-five seconds. In each case good fine toned positives were obtained. In this case the effect of alcohol in increasing the sensitiveness of the collodion was strikingly illustrated, whilst the respective changes of colour were very significant as to the chances of stability in each sample.

A continuation of this experiment was interesting and confirmatory of all my experience as to the effect of bromides. I divided each of these samples, and to half of each added a bromide in the proportion of from half a grain to a grain to each ounce, the first result of which was a slight milkiness and subsequent precipitation of, I presume, bromide of potassium. On subsidence I tried each bromidised half against that simply iodised. The alcoholic sample, requiring when simply iodised ten seconds exposure, required only three seconds with the addition of a bromide. A similar or still more marked increase of sensitiveness occurred in the other samples. The silver bath was an old one, to which no addition of nitric acid had ever been made. The developer proto-sulphate of iron

acidified with acetic acid. These facts seem to controvert the idea frequently expressed, that bromine is an accelerator only in the strict absence of organic matter, and where nitric acid is used in the bath and developer.

To return to my own practice in the positive process. The collodion I generally use, stands thus:—

Washed ether, pure or methylated s.g. from 720 to 750	1	ounce.
Alcohol s.g. 820	1	„
Iodide of cadmium	3	grains.
„ ammonium	5	„
Bromide „	1	„
Soluble cotton	10 or 12	„

I use these proportions with spirit of the strength named, which is generally easily procurable. Where absolute alcohol can be procured a much larger proportion of alcohol can, as I have already said, be used with advantage.

This collodion gives a creamy film in the bath, and under ordinary circumstances yields a picture possessing vigorous lights, with delicate half-tones graduating into rich transparent shadows.

I find, however, as I think every photographer has found, that no formula will work equally well under all circumstances, that apparent changes in the chemicals frequently occur without the intervention of any preventible cause. The nitrate bath especially appears to be subject to these vagrant fancies, and after giving a certain class of pictures one day, refuses, under apparently precisely the same treatment, to yield the same results in a few hours or days afterwards. As after once making a nitrate bath in proper condition I do not like to tamper with it, I generally find the simplest way out of the difficulty is the use of another sample of collodion. With this view I generally have in working condition several bottles of collodion, each possessing different characteristics. A valuable means of producing these modifications in the collodion exists not only in varying the base and amount of the iodiser, but especially in varying the amount of bromine. The action of bromine in positive collodion is not simply in accelerating or increasing the sensitiveness, but also in decreasing over-intensity and producing half-tone and softness. By keeping samples of collodion, some of which contain a large amount of a bromide, and produce corresponding excess of half-tone, and others with a small amount of bromide, and great intensity and contrast between lights and shadows, I find I am generally able to meet the changing circumstances caused by varying light, temperature, and condition of the nitrate bath. If the circumstances be conducive to the production of a feeble picture with excess of half-tone, I find that by using a collodion iodised with potassium and a small portion of bromide I can generally obtain at once sufficient intensity. On the other hand, if excessive intensity be the fault, I find that by using a collodion sensitised with ammonium or ammonium and cadmium and a full portion of bromide that softness and half-tone are obtained.

It is necessary to observe, however, that I have generally found a tendency in bromides to injure slightly the tone and brilliancy of the picture. Another effect of the addition of bromides, which I have invariably found, and have never seen any reference to, is its influence in producing a clean picture. Samples of collodion which have yielded dull, spotty, streaky-looking pictures when simply iodised, have given results clean and perfect on the addition of half-a-grain or a grain to the ounce of bromide. I find also that collodions which, simply iodised, have become seriously deteriorated in a couple of months, have with the addition of a bromide remained in perfect condition or have even improved at the end of six months.

I have tried some experiments with the addition of a chloride to collodion for positives, but without sufficiently satisfactory results. I have been inclined to think that the tone of the picture was improved by the addition, but have not repeated the trials sufficiently to speak with certainty.

Sometimes with a collodion quite new I find the blacks improved by the addition of a few drops of tincture of iodine. Still better than this for the purpose I have found the addition of about a drop to the ounce of hydrobromic acid, which rapidly produces on the collodion the effect of maturity.

(To be continued.)

PHOTOGRAPHIC PRINTING.

By A. J. Melhuish.

[Read at the Blackheath Photographic Society, 19th November, 1859.]

There are, I think, few things which appear more easy at first and more difficult as our experience increases than photographic printing. I well remember my first picture: it coloured rapidly a rich purple brown, not a tinge of yellow in the sky, and I thought that, although the negative process was rather troublesome, positive printing was easy and certain: little did I then conceive how much I had to learn ere I could produce the same results at will. I have now, after much experience in this branch of photography, become acquainted, I trust, with every difficulty connected with it, and I am anxious this evening to impart, as briefly as possible, to those of us who are not yet initiated in these mysteries all that is really necessary to practice this branch of photography with certainty and success. I may here mention that I shall confine myself, this evening, to a purely practical view of the subject; not that I undervalue the efforts of the chemist and the philosopher—indeed nearly all our hopes rest on them—but that I think it well to leave this for the performance of abler hands.

It will assist us in forming a clear view of our subject if we consider, separately, each object we wish to attain in photographic printing, and the means best calculated to secure it.

1. Having prepared a *good* negative, our first care should be so to protect it by varnish that a large number of copies may be printed from it without injuring the film. There is perhaps no better article at present made than that known as the French varnish. It requires the plate to be warmed when applied, and left about a day to get thoroughly hard.

2. As, unfortunately, our negatives are seldom perfect, our next object is by the process of doctoring, to hide as much as possible whatever defects there may be; this, I am aware, many object to, but as I am at a loss to see any foundation for such objection, I shall not stay to consider it. When a negative has been sufficiently exposed (a thing, by the bye, of most uncommon occurrence), the sky is generally so weakened by excess of light that it requires filling in, or as some term it, stopping out: the best thing for this purpose is a mixture of lamp-black, of neutral tint. I use Reeves' moist water-colour tubes, with a little gall. It is sometimes required to shade some portion of the picture which prints too dark, such as, for instance, the face of a portrait: this should be done by applying on the plain side of the glass a little lamp-black, and when nearly dry, softening it with the finger or a piece of rag; many a negative, otherwise lame and poor, may be made to produce brilliant prints by judicious application of this method of treatment. Having done all the shading required, varnish again with amber varnish; if shaded on the back, it is well to varnish that also. Should the sky ever become sticky, sprinkle it with whiting.

3. Our object now is to obtain a sheet of sensitive paper which will give as good a proof as possible. This I find (provided the positive paper is good) depends much on the amount of silver deposited on the surface of the paper; I therefore float the paper on a seventy-five-grain solution of nitrate of silver for about two minutes; hang up by one corner, when nearly dry, float again for the same time, and hang up by the opposite corner. I may mention that a strong negative requires to be printed in a strong light, and *vice versâ*.

4. Having obtained a print of sufficient intensity, our next operation is to tone and fix it, and upon this part of the process the beauty and permanency of the print mainly depends; up to this point all is easy and certain, but now phenomena of the most peculiar and diverse character appear. Now is the time to produce that "abominable yellow" which so deeply affected Mr. Sutton. Now spots scarcely visible become first stars, then comets, with long flowing tails. Now we may obtain that green—that *strange* green—which is too well known to need description, and which, for want of a better name, I would call *the old hypo' green*. Now delicate copies of the cuticle may be seen delineated upon the sky, and now may be witnessed that interesting phenomenon of brown spots, growing out of nothing—indeed there is scarcely any limit to the spots and stains and sickly hues which it is our privilege occasionally to witness at this stage of the process; but on the other hand, now may be produced a picture so chaste, so exquisite, so truly beautiful, that I know nothing that will bear a comparison with it: there is a transparent bloom upon a fine albumen print that is seen nowhere else. The following are the two methods I now adopt and strictly adhere to—the first, when a purple or reddish-brown is required; the second, when a violet tint is preferred:—First, wash the print in common water; fix in *new* hypo', four ounces to the pint; then tone in a new bath of—gold one grain; nitrate of silver two grains; hypo' half-an-ounce; distilled water one ounce. First dissolve the hypo', then add the gold, and last the silver. Warm the solution in cold weather.

Second, wash the print with *particular* care; tone in—gold one grain; carbonate of soda one grain; distilled water one ounce;

in a few minutes the print is toned, and then fix in — water one pint; hypo' two ounces: leave it in this bath about five minutes.

5. Having obtained a perfect print, our only object now is to keep it so; consequently we stop the action by carefully washing out every trace of chemical which does not form a portion of the picture. A print should not be washed less than twelve or more than twenty-four hours; the water should be changed constantly, and the print wiped often on both sides with a sponge. Respecting the failures, the small spots may generally be avoided by keeping the paper quite dry, and, if possible, warm until it is toned; the "abominable yellow," by washing the prints before toning them, and the detestable green, by using the gold and hypo' bath *new*.

Having had occasion several times to use the word *negative*, as applied to photography, allow me to protest against this absurd misnomer. Many an one who has no practical knowledge of photography might understand us if we told him that we printed our picture from a *reversative*, whereas, it is impossible to convey the faintest idea of what we mean to such an one by the astounding assertion that we produce our positives from negatives. When whilst washing our picture we see the film slip quietly off the plate into the sink, then indeed may we boast a negative; but let us no longer call that a negative which produces such positive results.

NOTICES OF RECENTLY PUBLISHED STEREOGRAPHS.

Views in China.

NEGRETTI & ZAMBRA, Hatton Garden, and Cornhill, London.

[SECOND NOTICE.]

HAVING disposed of the principal figure subjects in the series before us, we turn to the other classes.

Next in interest to the inhabitants we regard their idols and the temples; hence we come to

THE JOSS (No. 25), which represents the Goddess of Fecundity. The idol was presented to the temple by one of the Chinese Emperors, and is held in the greatest veneration, especially by the female inhabitants of Canton. Behind the principal idol are located several smaller ones, and on the ground before it are placed plants in vases as votive offerings; but their dried up and withered appearance does not say much for the attention they have received.

THE JOSS HOUSE (Nos. 23, 24, and 27), are different views of the building, which received considerable damage during the bombardment, not so much from the fire of our troops as from the act of one of the Braves, who threw a bag of gunpowder into the building under the impression that it was occupied by some of the barbarians. The explosion demolished a considerable portion of the edifice. It is richly decorated with carving and other embellishments, partaking largely, however, of the grotesque. This is best seen in No. 24, which is a front view of the principal entrance.

THE TEMPLE OF THE GENII (No. 8), is peculiarly Chinese in aspect, and the slide will certainly be a popular one. The building is situated in the Tartar quarter of the city, and it is to be regretted that it has suffered materially during the bombardment of Canton, the inhabitants of which hold this temple in great veneration. The quaint character of the structure and the agreeable contrast of light and shade render this subject extremely pleasing. A general distant view of this temple is found in No. 12, in which it forms the principal feature, and is there seen to be surrounded by a clump of tall trees. We are informed by the description that the building contains the largest bell in Canton, which is regarded with superstitious awe as foreboding evil to the place whenever it is sounded. During the bombardment a shot struck the bell and cracked it, and the sound emitted was interpreted as the knell of the city's prosperity. From the upper part of the last named, the panorama which forms the subject of No. 10 was taken. The view extends over an extensive range; and although the houses, for the most part, present a very mean appearance from being interspersed with some large sized trees, and here and there a structure of a higher character, together with the distant wooded country, the whole composes into a sufficiently pleasing subject. In the centre is THE MUSSULMAN PAGODA, said to be built by a son or brother of Mahomed, who first introduced Islamism into Canton. The structure itself is one of very little interest, being merely a tall circular shaft without window or any visible opening of any kind, and crowned with a smaller shaft, also circular, presenting much the appearance of a lighthouse.

THE NINE-STORIED PAGODA (No. 29), on the contrary, is peculiarly interesting and thoroughly Chinese in its architectural character. It is octagonal in form, and each storey being somewhat smaller than the one beneath it causes it to taper upwards. Although originally richly gilt and painted, as well as ornamented with elaborate carved work, it is now in a painful state of dilapidation, so much so that it would be impossible to ascend the spiral staircase which leads to the top. Much to the consternation of the population, an iron model of the pagoda, which until lately surmounted it, fell down; the feeling will be understood when it is known that a superstitious tradition was in existence that, whenever the model should fall, the city itself would fall into the hands of the barbarians.

THE SMALL PAGODA (No. 28).—On the south-east side of the city is an edifice of a different aspect, being only of three storeys in height, octagonal in outline, and picturesquely situated on an eminence beyond the walls of the city, a portion of which is apparent in the foreground of the picture. The pagoda itself is now in the occupation of a detachment of British troops, and in the distance is seen a range of mountains, known as the White Clouds Mountains.

THE FIVE-STORIED PAGODA (No. 5), now occupied as a barrack for the allied troops, is situated on the extreme northern point of the city walls, and in this direction the general level of the country seems to be interrupted by a series of very respectable hills. The residences located on the city walls appear to be very characteristic of the place, and the slide is an extremely pleasing one. The pagoda itself is not at all imposing, and reminds one of the grand-stands at some of our race-courses.

We must, for want of space, pause for the present, but purpose in a future number returning to the subject, as there are many more of the series that deserve particular notice. In the meantime we cannot do amiss in advising those of our friends who are in search of some acceptable article as a Christmas or New Year's present for a friend, to procure this truly valuable collection.

Meetings of Societies.

LONDON PHOTOGRAPHIC SOCIETY.

AN ordinary meeting of the above Society was held on Tuesday, the 7th instant, HENRY WHITE, Esq., in the chair.

The minutes of the last meeting were read and confirmed.

Several gentlemen were duly elected members of the Society.

The lists of retiring officers and proposals for re-election were then read, and are now affixed to the walls of the meeting-room.

MR. ENNEL said that the few things he proposed to have the pleasure of communicating to the Society were, to the best of his knowledge, new to photography, and, of course (as he thought), improvements. He proposed to follow the usual order of photographic operations, and state his remarks just as they occurred to him: he might now and then digress, but there would always be certain landmarks sufficiently salient by which he could find his way back again. He would begin with the first, and which is a most important operation — that of cleaning the plates, for which a special preparation has been advertised. We have powders and liquids on the one hand, and simple washing on the other, and they are all very good in their way. We may very frequently adhere strictly to a rule and yet violate the principles upon which that rule is based. There are many principles involved in cleaning plates; he would mention there was hardly a substance which does not adhere to glass, indeed, he knew of no substance that did not adhere, and the attraction by heat was more or less increased with different substances. The question was how to get those foreign substances away from the plate: with simple washing he could not manage it, the friction between the fluid-water and the plate is so very small that it does not overcome the attraction of adhesion; it was like the old trick which puzzled children so much — that of putting a shilling in the palm of the hand and attempting to brush it off with a stiff cloth brush, the friction not being sufficient to overcome the adhesion between the shilling and the palm of the hand. There were a great many instances in which the water did not wash away the adhering substances; for instance, the developing glass could not be washed out clean by water or acid without friction — acids give a deposit, and a bottle-brush or its equivalent must be resorted to. A feather by its centrifugal force will clean it. Washing a plate under a tap did certainly not appear to him to be the right way, because the drippings on the glass will afterwards adhere to it; it is much better to immerse it in water sideways, so that all the deposits shall sink down to the bottom: however, washing gave trouble, and, after many experiments, he found nothing better than the old tripoli rubbed on with a roll of flannel and immediately rubbed dry with linen, and that operation was very simple indeed when the cleaning board was used. There were many cleaning boards in use, but one he exhibited to the meeting he considered an improvement.

MR. ENNEL then referred to the coating of plates, upon which a great deal had been said. For small plates he did not consider it signified much whether you coated the plate by pouring on in the centre or at the side. For large plates he preferred coating from one side, just in the same way as he poured on the developer, and that avoided the double layer of film in parts of the plate so frequent in summer, especially in stereoscopic slides. He exhibited a collodion bottle by Hughes, and another by Brown, of Farringdon Street, which did not allow the film to

set in the neck, the vapour of the ether keeping it in solution: he secured his collodion bottles by a fillet or strap of india-rubber, which prevented the ether blowing out the stopper. He then proceeded to the dipping, and urged as a reason for preferring the "poor" glass dipper over the silver wire dipper, that though the glass broke it did not bend as did the wire, and the glass was the cleanest of the two. It had been urged that the wire did not adhere to the plate as did the glass dipper; but he contended that the adhesion was an advantage, and by sliding the plate off over the bath, one wiped the plate against the edge of the dipper, and saved an immense deal of silver. He was constantly in the habit of adopting that course. After immersing a plate he never touched it with his fingers, but took it out with what is called an American clip; then scraped it upon the dipper; then put it upon blotting paper for a while; then inserted a piece of blotting paper between the lower edge of the frame and the plate, so that the blotting paper touched the front of the frame; he then bent the paper over to get rid of the clip, and the plate is ready to slide into the camera. He had the camera at the meeting, because it had been the subject of discussion some time ago. After exposure in the camera he did just the same with the back, so as not to touch the film, and by using the clip while developing he had no pyrogallic acid or silver upon his fingers, which was an advantage, although some persons thought it right to carry about in the world the photographic sign upon their finger ends. He (Mr. Ennel) then exibited his universal levelling stand. Supposing the negative to be varnished, or not, according to the circumstances, although he might say that there was one negative which must be varnished, and that was when it was strengthened by bichloride of mercury; without its being varnished the mercury will find its way to the silver in the paper when brought in contact, and fill it with spots. In printing he understood that many negatives were broken in the ordinary pressure frame; he never had any broken because he never used the printing frame. He employed instead a mahogany board, with a cloth over it, and with a series of clips, which he produced, in which the fulcrum was so situated as to allow of their being put standing up or laid down. Mr. Hannah, of Brighton, he asserted, does the same, except that he uses plate glass. His presses were safe, cheap, portable; did not take up much room, and were very convenient for vignetting. Another operation which calls for the application of the clip is the sensitising the paper, when, instead of taking it out with the fingers, it is best to take it by the corner with a clip, place it upon an overhanging shelf, and then there is no more trouble with it, except to put one end of a small thin slip of bibulous paper about one inch long, and very narrow indeed, just in contact with the lower corner of the paper to draw off the lingering surplus silver bath. When the prints are obtained and washed they are hung up to dry in the same manner.

Upon referring to the washing dish, he observed a principle that he imagined had not before been remarked upon. Mr. E. then produced a large, flat, circular, yellow earthen dish, with a hole drilled through its side, into which, by means of gutta-percha, was cemented a glass syphon. Above the dish, from a tank, hung another syphon, with a regulating clip holding the india-rubber orifice, which is convenient when working in a dark room, as the supply can be regulated, the water kept constantly in motion and ever changing. The water thus run off requires to be precipitated. It is convenient to filter the bath by means of a regulating clipped syphon discharging itself into a funnel, inasmuch as once set to work it goes on, requiring no attention, and producing no stains and avoiding all spilling.

In testing the bath, Mr. E. had simply a narrow glass tube drawn out to a point, with an elastic ball at the other end, by which means he drew up into the tube twenty or thirty drops, as might be necessary, of a strong solution of salt, say thirty-two grains to the ounce, so that five grains of which will precipitate one grain of silver. Upon pressing the ball at the top, the solution will be *forced* out at pleasure, drop by drop, as long as precipitation takes place, giving the strength of the bath. It was not a very nice mode of testing, and would not do for assaying; but served the purposes of photography, and was an expeditious process.

Upon the subject of the dissolving of salts, it was a well-known fact, and daily practised among chemists, as is seen in the trough of the electrotype bath, to suspend the salt, because the fluid around it becoming saturated also becomes specifically heavier; and in the case of salt at the bottom, the heavier saturated fluid will surround the salt, and take up no more unless you disturb it; but by suspension, as fast as the fluid around the salt becomes saturated, and consequently of greater specific gravity, it will fall to the bottom, being replaced by a fresh supply of fluid around the salt, and so on until the whole of the fluid becomes saturated. It was the practice with salt to shovel it into baskets, and to lower them with ropes to the surface of the water, when the same process went on. With gum-arabic it was very convenient to tie it in a muslin bag, and suspend it, as it then became more quickly dissolved, filtered itself, and avoided the breaking of glass rods in the awkward stirring from the bottom. Professor Taylor had suggested to Mr. E. to try the effect of suspension of nitrate of copper, with some nitrate of copper at the bottom of the vessel; and this experiment Mr. E. exhibited with a glass test-pipe, showing the blue stream falling. What made the experiment interesting to photographers was, that it clearly exhibited the process that was going on in the dissolving of pyroxyline, which is a process of perhaps three or four weeks, whereas, if the pyroxyline be dissolved by suspension, it may be iodised the next day. Mr. E. exhibited the process of solution of pyroxyline by the ordinary method and by suspension, using in each case three ounces of ether, first saturating each quantity of fifty-four grains of pyroxyline in one ounce and a-half of alcohol. One quantity of fifty-four grains he immersed in the ether, and the other he suspended in a piece of cambric, though he preferred Irish linen. By stirring the portion in immersion with a glass rod it was dissolved immediately, but could not be seen through; while in the case of the suspended pyroxyline, in five minutes it was not only dissolved but bright and clear; and Mr. E. stated that if the linen were sufficiently fine, the solution might be iodised immediately; and if the bag were preserved, plain collodion could be kept ready for use to dress wounds, which was a desideratum to photographers who were constantly using cyanide of potassium. Mr. E. then exhibited the means of drawing off the supernatant liquid from the refuse after washing without disturbing the precipitated chloride of silver. He did this by means of a syphon, with its end kept floating on the surface by means of an india-rubber ball, with a pin attached to prevent its descent into the precipitate as the supernatant liquid ran off. Mr. E. then, by means of a Florence oil flask, with its neck inverted and suspended in a funnel with filtering paper in it, exhibited a self-supplying and self-stirring filter. Mr. E. also stated that he believed it was not generally known that chloride of lime would remove silver stains if afterwards washed with hyposulphite of soda.

The CHAIRMAN announced the presence of M. Joubert, who had kindly promised a present of some proofs taken by his new process.

M. JOUBERT then exhibited a portfolio of prints produced by his process, which excited very general admiration — one a representation of old stone ruins, which being placed under a hand lens exhibited none of the granulation so objectionable in ordinary carbon prints.

The CHAIRMAN said, if all we have heard of this printing process be correct, it promises to revolutionise the whole photographic system of printing.

Mr. SILVY presented to the Society three large and very fine prints of his own production.

[It would appear from the preceding that Mr. Ennel had not a very exalted opinion of the photographic skill of his audience. As a lecture to *tyros* in the art it might have been pronounced good — and as we have readers who are but novices as yet we report it — but, as a communication to the Photographic Society, we certainly consider that it partakes largely of the ludicrous. Surely Mr. Ennel cannot have mixed much with his *confreres*, or he would have been aware that there was really scarcely anything of novelty in his remarks.—ED.]

NORTH LONDON POHTOGRAPHIC ASSOCIATION.

THE ordinary monthly meeting of the Association was held at Myddelton Hall, on Wednesday, the 30th ult.; GEORGE SHADBOLT, Esq. V.P. in the chair.

After the usual business of the Association had been disposed of, Mr. G. W. Simpson read a paper *On the Positive Collodion Process*, with some remarks on the alabastrine process, illustrated by a large number of specimens. [See page 312.]

A vote of thanks was given to Mr. G. W. Simpson for his interesting paper; and a discussion ensued on the permanency of pictures taken by the alabastrine process. Mr. Simpson informed the members that many of the specimens on the table had been taken more than three years; and during that time had been standing on a shelf unprotected by glass or case; and although exposed to atmospheric influence for so long a period, there was no perceptible change, or deterioration in them. He thought this was a good test and proof of their permanency.

Mr. HUGHES wished to know whether the want of brilliancy in some of the coloured *non-inverted* pictures was a general result in this process.

Mr. SIMPSON considered that it arose from the *penetrating varnish* used when preparing the non-inverted pictures, slightly disturbing the powdery surface of the film, rendering it less radiative of the light than before its application: it was not always the case, it might arise from the original picture before the use of the alabastrine solution not being adapted for that process.

The next subject discussed, arising out of the paper that had been read, was the glass used for photographic purposes.

The CHAIRMAN stated that he had examined some of the glass mentioned by Mr. Wall and others at the late meeting of the South London Photographic Society [see page 299], which though very white and brilliant to the eye, did not as a rule admit of the production of negatives without either being fogged or stained. On looking at some samples in Messrs. Cotton and Wall's establishment, from the appearance presented, he was induced to examine the surface by the aid of a powerful lens, and found, as he had

expected, that it was imperfectly polished, being covered with a number of minute depressions, each one forming a centre of chemical action.

Mr. HUGHES stated that some time ago he had among his stock of glass a description that was exceedingly white, very smooth on one side, but hillocky, pimply, and rough on the other, he had taken some of his best pictures on this glass; it gave an exceedingly bright image with great depth of tone, and whenever he wanted to produce something extra good, he always selected this glass, but it was necessary to be very particular as to which side was coated with collodion.

Mr. A. GOSLETT had no doubt, from Mr. Hughes's description, that it was "chrystal sheet;" it was of course necessary to use the right side, for if the uneven side were coated with collodion it would produce a very unsatisfactory result. The best glass, in his opinion, was "*polished* flatted crown:" this is flatted crown polished by hand, but previously flattened by fire, which he explained was done by passing a hot iron over one side of it to reduce irregularities.

Mr. D. W. HILL always used patent plate, after losing many good negatives in flatted crown by breakage in the printing-frame.

The CHAIRMAN then directed attention to the next point of importance noticed in Mr. Simpson's paper, viz., the cleaning of glass. In his opinion there was nothing better than old collodion.

Mr. HUGHES remarked that the only objection was its unpleasant effect upon the eyes.

Mr. SIMPSON had used it, but thought the Tripoli mixture, the formula for making which he had given in his paper, was preferable.

The CHAIRMAN said that with regard to the use of the methylated spirit in the collodion, he widely differed from Mr. Simpson, considering it highly injurious to the nitrate bath. Several members were of opinion that methylated spirit was extensively used in the manufacture of collodion.

Mr. HUGHES said there was no difficulty in ascertaining whether such spirit were used, all that was necessary was to let a little collodion evaporate in the hand; the unmistakeable smell of tar would remain when methyle had been used.

Mr. SIMPSON had examined a large number of collodions, and almost all contained methyle. A few makers were named whose collodion did not contain it.

With regard to the method of iodising the positive nitrate bath the CHAIRMAN said that the method adopted by Mr. Simpson was, in his opinion, decidedly the best (that of leaving in the bath for some time a plate coated with the collodion to be used), as the bath thereby obtained not a simple iodide only, but a first dose of the other salts with which the collodion was sensitised, so essential to the production of a good picture.

A discussion then arose relative to iron developers.

Mr. HUGHES and Mr. SIMPSON were both of opinion that the addition of sulphuric acid to the developer, especially when acetic acid was also used, produced a dead flat picture, or one covered with silver spangles — in fact, it had all the disadvantages of nitric acid, without any of its counterbalancing advantages.

Mr. D. W. HILL stated that a friend of his had produced some excellent pictures by development with formic instead of citric acid.

Mr. WALL also stated the same fact; but the general opinion was that these good results were merely accidental, and produced in spite of its presence, formic acid having a tendency to fog and produce dirty pictures.

Mr. D. W. HILL had also seen good positives developed with protosulphate of iron, without the addition of any acid.

Mr. SIMPSON had in his paper remarked that he thought the beneficial effects of bromides had not been noticed.

Mr. HUGHES stated that he believed he had first called the attention of Mr. Hardwich to the advantages derived from its use, and in the course of experiments he found there is a tendency in bromide, in certain conditions of the collodion, to greatly influence and modify the effects of iodide. [See THE PHOTOGRAPHIC JOURNAL, No. 93, vol. vi. page 111.]

The CHAIRMAN exhibited a number of stereoscopic pictures of China, published by Negretti and Zambra [see p. 315], and a remarkable picture of the spire of Salisbury Cathedral, by Mr. Sedgfield, which appeared horribly distorted in looking at it in the usual position of the stereoscope, owing to excessive "cocking up" of the camera; but on changing its position and looking upwards, the picture assumed a natural appearance.

The CHAIRMAN also exhibited several stereoscopic sunset pictures, by G. W. Wilson, of Aberdeen, with the sun directly in front of the camera — a position in which it has been hitherto considered impossible to take a good impression. These proofs were very much admired for their brilliant and artistic effect. In addition to the above, he exhibited a small print, on paper, by Mr. Church, of Glasgow, prepared six weeks ago, and kept in a case similar in principle to that of Messrs. Marion and Co., and described at p. 66 of the present volume.

A copy of the PRESENTATION PHOTOGRAPH* for the present year was handed round: the subject, "Tintern Abbey," by Bedford. This elicited general approbation, and a vote of thanks was given to the gentlemen of the sub-committee for the good taste and judgment displayed by them in the selection.

Mr. D. W. HILL exhibited a picture taken by the Fothergill process, with the addition of one grain phosphate of ammonia to the ounce of albumen solution.

Mr. WALL kindly presented a stereoscopic picture of the costly bedstead lately presented to the Queen, for which the thanks of the meeting were accorded to him.

Captain Higginson and Mr. Henry Squire were duly elected members of the Association.

Two of Mr. Moginie's tents were erected in the room for exhibition — one a tent only, the other camera and tent combined, weighing only 9 lbs. They attracted a considerable share of attention, and long after the meeting had closed, many of the members were discussing the merits of both. [See THE PHOTOGRAPHIC JOURNAL for July 1st, page 160.]

The meeting adjourned to the 28th instant, when some *important improvements* in cameras and other apparatus will be exhibited and explained.

BLACKHEATH PHOTOGRAPHIC SOCIETY.

THE eighteenth ordinary meeting of this Society was held on the 24th ultimo, at the Golf Club House, the President, J. GLAISHER, F.R.S., in the chair.

After the usual business had been transacted, Mr. A. J. MELHUISH proceeded to read a paper "*On Photographic Printing.*" [See page 314].

At the conclusion of the paper a vote of thanks was tendered to Mr. Melhuish.

Mr. Robert Peter Napper was proposed as a member of the Society; after which the meeting adjourned.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE second meeting for the session of this Society was held on the 7th instant, at the rooms of the Literary and Philosophical Society, 36, George Street, W. C. WILLIAMSON, Esq. presiding.

Mr. Charles Hebert was elected a member of the Society.

Mr. MABLEY read a paper on *The Focus of Lenses*, which had been written by GEORGE SHADBOLT, Esq., for the Society. [See page 311.]

A vote of thanks was unanimously passed to Mr. Shadbolt for the paper which had been read.

Mr. DANCER having contributed an oxyhydrogen lantern, with the requisite apparatus for the exhibition of transparencies, in accordance with the arrangements in the circulars, the discussion on Mr. Shadbolt's paper was adjourned until the next meeting.

The following members brought transparencies, taken by themselves, for exhibition: — Mr. Patterson, Mr. Wardley, Mr. Young, Mr. Mabley, Mr. Taylor, Mr. Dancer, and Mr. Mann.

The lantern contributed by Mr. Dancer being one of the best construction, and comprising some improvements by himself, for the purpose of exhibiting photographs, the pictures appeared wonderfully bright and clear upon the screen. The pictures were also almost all photographs of the first-class, forming a most interesting exhibition, and were much applauded by those present. The attendance was very numerous.

After a vote of thanks to Mr. Dancer, for his contribution of the oxyhydrogen lantern, and to the Vice-President, Mr. W. C. Williamson, for presiding, the meeting closed.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

THE monthly meeting of this Society was held on the evening of Tuesday, the 29th ultimo. The chair was occupied by Mr. BROWN, the Honorary Treasurer.

There was no special business, nor had any paper been prepared for reading and discussion. One of the members of the Society, however, having been very successful in photographing several high-class engravings, presented copies of these to his fellow members, and some conversation followed regarding the difficulties incidental to this branch of the art.

* A copy of this beautiful production will be presented to every member of the Association. It is a photographic gem.— ED.

Practical Instructions on Coloring Photographs.

By Alfred H. Wall.

CHAPTER VI. *(Continued).*

THE EYES.

Take, then, the eyes first; carefully and patiently strengthen the lines of the upper lid; *don't hurry;* speed will come with confidence, and confidence with practice. Is the lash of the upper lid dark and long, remember that it falls upon and blends softly with the shadow upon the cornea or white; if it is light, remember that it is made visible by the self-same shadow, and can never be truthfully represented by a mere black line. As the cornea retires from light, observe that it falls into delicate shadow, rendered thus faint and delicate, because from the nature of its surface, it receives a strong reflected light. The iris is outlined, sometimes with a clearly-defined line and at others with a faint touch dying into the white; identity of expression is in no small measure dependent upon the due preservation of this peculiarity — a fact I first discovered from studying photographic portraits, and one strangely overlooked by many very eminent artists, all of whose eyes are defined one way, viz., either with or without a distinct line round the iris. In such points as this it is that photography becomes the artist's best teacher. With tender touches gradually strengthen the shadows beneath the brow and that below the eye, or the lower eye-lid, if the latter be full. Upon the proper depth of this shadow depends the characteristic prominency of the eye, its consequent expression, and, therefore, the preservation of likeness. Now, with a few vigorous touches, put in the pupil of the eye; finish the iris, carefully preserving its transparency by strengthening the light reflected through its shadowed side from the lighted portion (see maxim 46). The gleaming character of the fluid found in the corner nearest the nose must be faithfully preserved. Remember that what is called "the white of the eye" is not by any means white, for, being overshadowed by the thickness of the eye-lid and the length of the projecting lash, and being in part concealed from light by its receding nature, it exposes a very minute portion of its surface to direct light; therefore, retain the delicately-shaded appearance it has in your photograph by keeping it down, and strengthening its shadows and tone in exactly the same proportion with the rest. The gleaming spark of light found on or near the pupil is put in with a minute touch of Chinese white. In the photograph this will very probably be represented by a glare of white, destructive of all expression, and giving the appearance of "a cataract." Much as this has been decried by artists, *it is truthful.** Painters, to give unnatural prominency to the spark of light, place its representative dot of white in the midst of dark touches; but in nature we find the spark of intense light, reflected from the eye, is situated in the centre of other light of increased magnitude and diminished intensity. Photography seizes the larger and inferior light, and represents its intensity *truthfully* with *white*, and, therefore, lacks the means of representing the increased brilliancy of the minute spark, which is consequently swallowed up in the white patch representative of the less intense light. *Bear this in mind, if you please, whenever your photograph represents polished surfaces.* Painters having only white to represent the most brilliant light, have recourse to art to force the brilliancy of their white pigments; but photography can claim no such assistance from its own resources. (See maxim 31.)

If you place your spark of light as the centre of another light graduating into the local colour or shadow of the iris or black of the pupil, you will produce an effect which I think is most true to nature; if you place it in the midst of dark touches you will obtain an effect most striking and pleasing to the uneducated eye. Without comment I leave to you the choice, which a few experiments may best aid you in making.

The cavity of the eye is generally observable — sometimes very distinctly, sometimes faintly, but always more or less. It is sometimes indicated by lines, sometimes by a mass of half tint, and sometimes by a very delicate and scarcely perceptible shadow. In either case its faithful rendering is of importance; so pray don't overlook its preservation.

* I remember reading in, I think, the "Quarterly Review" a most ably and powerfully written article upon photography, in which the writer, mistaking these broad white lights for positive high lights, ridicules them as exaggerated and untruthful. This author should have remembered that it is only by the degredation of minor lights that painters make white serve to represent the high lights, and although photography, lacking this power, cannot give high lights, the lights given are none the less truthful, both in regard to size and intensity.

THE NOSE.

Let us now take our lady or gentleman by the nose. Say we have a three-quarter view of a face to work on; the nose is relieved against the "cast shadow" or the shadowed side of the face. Strengthen with the same patient care I have before advised the shadow which outlines the nose; do so tenderly, with a light hand and a delicate touch, or we shall have a hard streak of black paint instead of a sweetly graduated shadow. (See maxim 7.) This done bring the shadow softly into the delicate tones between the nearest eye and the nose — *don't hurry*. Now touch the shadow under the nose, remembering that it is not a mere black patch but is composed of intense touches of dark, which give vigour of effect, of reflected light, and half tones; which prevents harshness and crudity. Examine your photograph carefully, and, if it be a good one,* you will see that this is the case. That done touch in the aperture of the nostril, gradually strengthening it until it is of the required intensity; it must not be too black, because not only is light reflected into the opening from below, but also through the semi-transparent flesh below the bone of the nose. In delicate children and females it will be lightest, in men and aged persons darkest. Trivial as some of these points may appear to the unthinking, the thoughtful artist has learnt to appreciate them at their full value, and I do not urge them upon your attention without having good reason for so doing.

The author of the preceding paper has, in order, to render his communications of greater practical value, kindly undertaken to criticise the work of, and give advice to, students in colouring, through the medium of these pages, for which purpose specimens may be sent, with a stamped and directed envelope *for their return, to* A. H. Wall, Esq., 11, The Terrace, Walworth.

J. G. — I am not aware. If I can procure the information it shall be inserted in the number for January.

John Blunt. — You have jumped at the middle of the ladder and missed it; why not begin at the bottom? — that is to say, with the lesson commenced in my last.

L. T., City. — Melt white wax in a clean pipkin; add turpentine; colour as usual; place the print against the window (unmounted of course), and carry a wash of colour over the back of the hands and face; then apply the wax (hot), and when dry mount it upon white card (the yellow will make it appear horn, and not ivory-like as you imagine).

Miss D. — The first book I cannot conscientiously recommend, but the "Harmonious Colouring" is a very excellent little work. Field's "Grammar of Colouring" is the best and cheapest. Your last question is very complimentary, but I am not the gentleman described as "the first photographic colourist of the day," and am anxious to know who is the first. You must test him as they do puddings. No one can blame you for seeking information wherever it is to be found: it is the right way to obtain it. I do not receive pupils just now, my days being so much occupied.

G., Daintree. — I have, with some trouble, ascertained how the new French pigments are made, but have not tested them. If you do so first, please to let me know the result. I have great hopes of the permanency and brilliancy of these new paints. The composition is — equal parts of purified yellow wax and linseed oil, with four-fifths of spirits of turpentine, and half the first quantity of common resin. The wax is dissolved in the linseed oil first, and the resin in spirits of turpentine, by heat: they are afterwards mixed and used as a vehicle with the ordinary oil colours. Thin with turpentine. I fear they will not dry very quickly. See my reply to "J. Blunt."

James Pearson. — It should have been "too black," or, better still, too dark and too cold in tone. This gentleman asks pardon for mentioning some remarks made upon these instructions, to the effect, in plain English, that either I (being a professional) am a fool to give information that will decrease the value of photographic colouring in the market, or a knave, professing to teach and doing nothing of the kind. Don't be startled, James, to see how ugly these remarks look thus translated into their true meaning. Tell the wiseacres who made them that monkeys are very cunning, but not very wise, and that cats are more celebrated for suspicion than any other beings. There are small minds which have so little information to spare that they never give any away, and artists who, being conscious of the ease with which they may be equalled or surpassed, are jealous of all rivals. I hope to prove myself neither one nor the other, to all my pupils at least. As to the remarks made by strangers — we must bear slander while we are here, and may as well do so patiently. You will be rather grieved that you repeated these remarks, perhaps; but I thank you for the laugh they provoked. It's very natural, you know, after all — *to some folks.*

* The student will perceive that I suppose him to be working upon a good specimen, and upon a subject posed and lighted after a style most commonly adopted. As I intend to take two or three such imaginary photographs, and go through the process of touching them in the above manner, any pupil of mine may, if so inclined, send a print of the photograph he is desirous of practising upon, and I will speak of that in the place of the imaginary specimen.

Letters to a Young Photographer.

No. XXV.

My Dear Eusebius,

There remains but little more for me to do in my task of initiating you into the arcana of photographic methods, manipulations, and processes. You have now a large field wherein to exercise your ingenuity, and when that is exhausted, you may turn to the cultivation of your taste, and I hope you will find an instructor as anxious for your welfare as myself. Like most verdant youths, you can quickly recognise a recipe or a formula, because you can reckon it off quickly at your finger's ends; but you are dull at comprehending the value of a principle. If you wish to become an artistic photographer, you must master the principles of art, and if you encounter as much trouble in finding them as I did you will regret rejecting my endeavours at smoothing your way over a very rugged road. The principles of mechanics and of chemistry you will find laid down with great precision and clearn ess by many able writers, but I cannot recommend to you a book wherein you will find a clear exposition of the principles of art. On that subject there is much dogmatism, absence of precision, and of induction. It offers as wide a field for conceited opinions and arrogant assumption, as politics and religion.

* * * * * * * * *

Now, my dear Eusebius, the curtain is about to fall upon this monologue. You know the proverb, that "no man is a prophet in his own country:" it applies to myself in an eminent degree. For many long years I have been professor of things in general in this country, and have reaped small gain and less honour. But I am happy to be able to inform you that I have lately received a curiously sealed packet, bound with coloured silk, heavy withal, which upon opening, I find to be a communication from China.

And lo, dear Eusebius, I must depart in the first ship that sails. Perhaps my next epistle will be dated from the Mountains of the Moon. Adieu, dear Eusebius. Farewell. *Leben sie voll. Addio.* Good bye, God bless you! *Au revoir.*

Photographic Glossary.

Varnish for Positives on Glass — Glass positives are backed with black varnish, or other black material, such as velvet. It is first necessary to protect the collodion film, and this may be done with albumen or solution of gum-arabic. The black varnish is composed of bitumen dissolved in camphine, or in essence of turpentine, to which a little wax is added to correct its extreme brittleness. The following is a good formula:—

Camphine	100 parts.
Bitumen, pulverised	20 „
White wax	4 „
Lamp-black	1 to 2 „

Dissolve the mixture by a gentle heat, shaking the bottle frequently; filter through flannel, and preserve in a well-corked bottle.

Wax — A well-known substance secreted by the bee, and by various plants. It readily dissolves in the fixed and essential oils, in boiling ether and alcohol, in turpentine, paraffine, &c. It is much used in the waxed-paper process in photography.

Varnish for Positives on Paper—Positives on albumenised paper, when mounted and highly varnished, appear as brilliant as when viewed under glass, and are, moreover, protected from atmospheric agencies, which sooner or later deteriorate them. In selecting the materials for a varnish care must be taken to remove all discoloured pieces of resin, as well as those of other qualities which fraudulent dealers frequently mix together. A good varnish may be prepared according to the following formula:—

Alcohol	100 parts.
Powdered glass (or washed silver-sand)	20 „
Mastic in tears, washed in alcohol	15 „
White elemi resin	8 „
Venice turpentine	8 „
Dammar resin	16 „

Spirit varnish does not, like turpentine varnish, improve by keeping; therefore, as it is quickly prepared, it should only be made as wanted. The addition of one per cent. of camphor preserves the varnish from growing darker, but the bottle containing it should be kept in the dark.

Whey — The serum of milk, which separates from the curdy or cheesy portion upon the addition of acids, &c. It consists of water, sugar of milk, lactic acid, and other substances. It is used to prepare the paper in positive printing by development.

Xyloïdin — A name given to soluble gun-cotton, &c.

Zinc — The iodide of this metal is sometimes employed in photography as a sensitising agent, but it is inferior to iodide of cadmium or potassium.

Foreign Correspondence.

Paris, December 9, 1859.

M. Niepce de Saint Victor has made another communication to the Academy, on the action exercised by light upon certain aqueous solution of substances previously experimented upon in the solid state. Dr. Draper had already shown that when a solution of peroxalate of iron is exposed to the light a gas is disengaged, and the iron acquires the property of precipitating salts of gold in a metallic state. An application of this fact was made in constructing a photometer, in weighing the quantity of gold reduced. Upon this hint M. Nièpce made the following experiments:—It is well known, that next to gallic acid, oxalic acid is among organic acids that which most readily reduces the salts of gold; but if we solarise a solution of oxalic acid, it then reduces chloride of gold more rapidly. It is the same with the other organic acids, which, in different degrees, can reduce the salts of gold, and even of silver uninfluenced by light. He next solarised a solution of nitrate of uranium in distilled water, and, separately, a neutral solution of organic matter. If the first solution is not neutralised by ammonia or yellow oxide of uranium, it will not reduce (at least in the same time of solarisation) chloride of gold, while in the opposite case it does reduce it.

As to the second solution, it gave no trace of reduction; this was owing, perhaps, to the substance not being sufficiently solarised, for it is certain that starch and gum can be partly transformed into *glucose* by the influence of light solely.

Now, if we solarise a mixture of nitrate of uranium and of neutral organic matter in solution, contained in a bottle which it entirely fills, and is hermetically sealed, this liquid reduces the chloride of gold and nitrate of silver after a very short solarisation. The reduction becomes stronger in proportion as the exposure to light is prolonged. There is, however, a moment when the reduction is at its maximum of effect: it manifests itself by a black colouration, which is produced in the liquor immediately nitrate of silver is added to it.

If the solarisation is further prolonged the liquid becomes grey upon the addition of nitrate of silver. It loses more and more its reducing power, and at last disappears altogether with respect to nitrate of silver.

But it is a singular fact that, if we remove the liquid from the action of light when it has attained its maximum of activity for reducing salts of silver, this liquid loses its activity in less than five minutes by agitation in the open air, by ebullition, or by a prolonged repose in the open air; but if, on the other hand, it is hermetically closed, it retains its activity.

With the solution of nitrate of uranium and organic matter, the liquid, under the influence of light, begins to be coloured green if the solution be acid, and violet if it is nearly neutral. If we continue to expose the liquid to the light, we perceive it to become slightly troubled, it then becomes opaline, and more troubled, till at length a precipitate is formed at the bottom of the vessel, and in this state it no longer reduces nitrate of silver, but it still reduces chloride of gold.

If the liquid in which the precipitate is formed be agitated, this precipitate is dissolved completely in less than five minutes, and it also dissolves after prolonged repose.

The action of light may be very favourable upon certain wines; it may impart the character of old wines to them on condition that the action of light be sufficient and not too prolonged, otherwise the wine contracts a disagreeable flavour.

M. Cordier communicated the following fact to the Photographic Society:—A plate coated with collodion, sensitised by iodo bromide of cadmium and an old silver bath, highly charged with ether and alcohol, was exposed to a moderate light for forty-five seconds. During sensitising the door of the operating-room was accidentally opened, but instantly closed. Upon developing it, the picture became a vigorous positive by transparency, while it remained negative by reflected light.

Correspondence.

STEREOGRAPHS.

To the Editor.

Sir,—Permit me to thank you for your valuable criticisms on the newly-published stereoscopic slides. There are many persons, like myself, who are far away from the metropolis, and who have no chance of becoming acquainted with what is being brought out as stereoscopic novelties except through advertisments, and I, for one, am quite tired of spending money on what I find when it arrives is just so much trash, as a rule. I have certainly met with one or two exceptions, but these are rare indeed. Your remarks are just what those situated like myself have been long wanting, critical and descriptive, and written in an independent spirit. To you I am indebted for all the best slides which I possess, for certainly without your notices I should never have known anything about them. I recently obtained, by the assistance of a friend who was visiting London, a number of the interiors by Mr. Sedgfield, which you noticed a short time back, and very much pleased I was when I looked them over. My particular object, however, in writing at the present moment is, to inquire whether you know of any good illustrations (stereoscopic) of the Cumberland Lakes, similar to those of Mr. Woodward's of Dovedale?—I am, Sir, yours, &c. T. C. B.

Bodlingham, 18*th November*, 1859.

[We are unable to afford you the information sought, and as the best means of obtaining it we publish your note.

We received, about twelve months ago, a specimen from a photographer (professional) in the district you mention, which was well executed as regards the negative, but a little tame in the printing. We cannot now recal his name; in fact, we are not sure that we were made acquainted with it. Doubtless, however, some specimens are to be had.—Ed.]

MEMORIAL CARDS.

To the Editor.

Sir,—Knowing that you are at all times glad to make public any little thing that may tend to advance photography and all connected therewith, I enclose a specimen of what I think a new idea (at least I have never seen or heard of it before) for the improvement of our memorial cards. I need not explain, as the specimen will show for itself. It would also be a nice way of getting up portraits of our deceased great men, such as Stephenson, Brunel, &c. Of course the style of the cards could be varied according to taste, and it would be an improvement were the oval or other shape to be cut in the card.

Should you deem this worthy of notice your mention of it in the Journal will oblige.—I am, Sir, yours, &c. WILLIAM J. HAWLEY.

Glasgow, 8*th Dec.*, 1859.

[The card enclosed with the preceding note is a black bordered one, with a tablet embossed thereon, in the centre of which a photograph of the deceased, in the medallion form, is attached, space being left for the inscription.—Ed.]

PHOTOGLYPHIC ENGRAVING.

To the Editor.

Sir,—I send for your inspection a proof from a photoglyph plate—the subject, *College Green, Dublin*—from what is called an instantaneous photograph, untouched, executed by Mr. Fox Talbot's new process.

I have from time to time tried all the processes for the engraving of photographic pictures, including the daguerreotypes; and, as a practical engraver and a photographer of upwards of twenty years' practice, I consider the photoglyphic process far superior to all others—in fact, I can produce with it all that can be desired in the representation of animate and inanimate objects, preserving the faintest tracery, the half-tone and gradations of tints, to the deepest shades, and in no way to use the graver except for the margin and name. At an early date I shall send you for publication the plans I adopt and some specimens.

I consider this the last of the many inventions and improvements made by Mr. Fox Talbot crowns the capitol of photography, and hope to see the day when her most gracious Majesty (an amateur engraver and photographer herself) will confer on Mr. Fox Talbot, the father of photography, some distinguished mark of her favour, for his invaluable services to this infant art—an art calculated to extend still further the education and comfort of her subjects, and to surround them with whatever is beautiful in science and in the useful and ornamental arts.

Wishing you and The Photographic Journal every success, I am, Sir, yours, &c. FRANCIS S. BEATTY.

16, *College Green, Dublin.*

[We have received Mr. Beatty's specimen, which shows considerable advance in photoglyphography, but there is still much to be done. We shall be obliged for his communication, as there are many who will be glad to receive hints in practising this promising art.—Ed.]

EUSEBIUS AGAIN.

To the Editor.

Sir,—Pray permit me to trouble you with one more short note. I am much gratified that my master has returned to the instruction he is so ably qualified to carry out, but I fear you have mistaken my object in writing to you. I do desire to become a photographic *artist*, but really did not perceive that novel theories upon abstract principles could be of much service to me in this regard.

With reference to my grandmother's letter, you must know that it originated in the fact of my master's gift of a "penny meerschaum and four ounces of the best 'cnaster;" and also that the dear old lady has a pious horror of hair upon the face, as, doubtless, she would have had of hair upon the head if she had been born a Chinese.

I trust, therefore, that my kind master will continue his pleasant and instructive letters, and receive back with his old cordiality his really earnest scholar, EUSEBIUS.

[We thought that it was only in the Emerald Isle that pupils dictated to their masters the method of teaching. We really fear you want to be a pupil of the "handle" school.

We are quite at a loss to understand your reference to your grandmother's horror, or what it has to do with *photography*. We fear that you have been trying your hand at a digression.—Ed.]

ANSWERS TO CORRESPONDENTS.

CHALLENGE.

We have received from "An Amateur" three specimens of landscapes from negatives, by collodio-albumen process (Taupenot's), with a challenge to other photographers to compare specimens by the same or other processes. We need scarcely say that we shall be most happy to receive and report on specimens sent in answer to this challenge. We are informed that the printing of "An Amatuer's" specimens have been done by Messrs. Frith and Hayward. We congratulate them upon having turned out something truly magnificent in the printing way; and can only say that, if they print thus as a rule, we think they will soon have more work to do than they can well accomplish.

Thomas.—1. No. 2. The last named.

Bailey.—See the article mentioned in our last.

Quixote.—It would be a work of supererogation.

J. C. R.—Too complimentary to publish. Thanks all the same.

R. B * * *—Not good enough to notice: we should only do you harm, as we always report as we find.

C. Turner.—Your stereographs have not sufficient merit for any extended notice, they are passable, that is all.

G. F. H.—You are too exacting; but as a *Liverpool* brother we will indulge you as soon as we can find time—no easy task.

Green.—See Mr. G. W. Simpson's paper in the present number. You want a larger bath; with so small a quantity as you name it is soon exhausted.

Convex.—The best work on optics that we know of is that by Coddington, but unless you are something of a mathematician you will not comprehend it.

W.—We have no further information than what we published relative to Mr. Lloyd's apparatus. We do not understand what question you desire to put "on cameras."

R. S. D.—What *defect* of vision do you refer to? Unless we misunderstand you, we differ from you entirely, and are of opinion that, excepting a person be *blind*, with one eye he can see as perfectly with the stereoscope as without. Neither more nor less.

W. Pae.—There is a chapter on colouring stereographs on paper in the new edition of a cheap pamphlet on "Harmonious Colouring as applied to Photographs," just published by James Newman, Soho Square, London. See also Mr. Wall's article on colouring.

James Hilditch.—Certainly the chances of staining are reduced by employing a glass dish in which to develop negatives, face downwards, provided the dish be *properly cleaned*. There is no objection to the employment of gallic acid for the purpose, except loss of time.

A Poor Photographer.—The availability of your condensing lens depends upon its focus, which must be *longer* than that of the combination by which you wish to enlarge, and it should be so fixed as to bring rays to a focus, *not* on the front lens of your portrait combination, but at its optical centre. See a paper in the present number on this point.

Alignis—1. Leamington; you well understand this allusion. 2. No objection. 3. Iodine in the collodion tends to render the action *slower*, is a remedy to some extent against fogging, in consequence of its setting free *nitric acid* in your bath, which you will find becomes more and more acid, and your pictures weaker and weaker. 4. Yes, a bromide in the collodion is decidedly useful, say half a grain to one grain of bromide of cadmium to each ounce of collodion. Too much bromide weakens the density of your proofs. 5. Add neither ether or alcohol to your nitrate bath, but coat a plate with the collodion you intend to use and leave it in your bath all night. 6. Not good. 7. You do not state whether your lens is a single or double combination, how then can we judge?

⁎ A great press of matter has compelled us to leave over several articles in type, amongst which are an article on Mr. G. W. Wilson's Stereoscopic "Scottish Gems," "Illustrated Description of the Achromatic Mirror Stereoscope;" "Notes of a Photographic Tour in the Holy Land," notices of "New Books," &c.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

EDITED BY GEORGE SHADBOLT.

VOL. VII.

LIVERPOOL:
HENRY GREENWOOD, 32, CASTLE STREET.
LONDON:
E. MARLBOROUGH & CO., AVE MARIA LANE; HORNE & THORNTHWAITE, 123, NEWGATE STREET.
EDINBURGH: JAMES WOOD, 130A, GEORGE STREET.
DUBLIN: J. ROBINSON, 65, GRAFTON STREET; G. MASON, 24, D'OLIER STREET.
PARIS: G. FOWLER, 6, RUE MONTPENSIER. NEW YORK: E. ANTHONY, 501, BROADWAY.

PUBLISHER'S PREFACE.

The present Volume completes the SEVENTH year of the existence of this Journal. This special fact must form an apology for the unusual intrusion of this notice on the present occasion.

The second Photographic Journal established in order of time, the Publisher has aimed at making it the *first* in point of excellence and of usefulness to the adherents of the Art-Science of Photography. How far this intention has been fulfilled it is left to its numerous readers to judge; but, if position, influence, and circulation be a criterion, THE BRITISH JOURNAL OF PHOTOGRAPHY has taken the lead among the Journals devoted to the Art.

On thus completing his apprenticeship to the cause of photographic literature, the Publisher presents his acknowledgments to the Editor and his *Confrères*, and to the regular and occasional Contributors to its columns (its correspondents embracing the most eminent names connected with Photography), for having enabled him to attain the foremost position.

The Publisher cannot forbear especially acknowledging his indebtedness to the esteemed Editor, Mr. GEORGE SHADBOLT, for his hearty co-operation, and for the thorough honesty of purpose and unwearied attention to the interests of the Journal which he has brought to the fulfilment of his editorial duties.

To Mr. T. F. HARDWICH, late of King's College—who is appreciated throughout the civilised world as a profound scientific chemist and popular and eloquent writer on Photography—the Publisher feels obliged for his lucid "Comments" on the chemical aspect of the science which appear periodically in these pages. Numerous correspondents have signified their high appreciation of Mr. HARDWICH's articles in this Journal; and to that gentleman its readers are indebted for much valuable chemical information not bearing his name.

Mr. S. HIGHLEY, F.G.S., F.C.S., &c., as Sub-Editor, has been indefatigable in his duties; and in the Art-phase of Photography, Mr. A. H. WALL has given in the columns of this Journal the benefit of his great experience.

The Publisher assures his readers that the arrangements for continued and, where possible, augmented usefulness are complete and ample in every department. In conclusion, he begs to thank that important section of his supporters—the Advertisers—for the large amount of favour bestowed on THE BRITISH JOURNAL OF PHOTOGRAPHY, and he has no doubt that their continued connexion will be mutually advantageous.

INDEX.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 109, Vol. VII.—JANUARY 1, 1860.

The Title announced in our last not having given entire satisfaction to the Proprietors of the Journal of the Photographic Society, we so far meet their views as to add to our announced title the word "British" as a prefix. The present Number, therefore, appears before the public as THE BRITISH JOURNAL OF PHOTOGRAPHY—a title at once distinctive, and yet bearing the impress of its former existence as closely as our understanding with the proprietors of the London Society's Journal will fairly allow.

In order to prevent confusion to our readers and further derangement of our plans, we have arranged matters so that the appearance and general aspect of the Journal will be so like to what it has been during the last twelve months, that unless special attention were particularly directed to the point we question whether there are many of our readers who would have detected any change. In this we believe we are acting prudently for the interests of all parties; for there never was a question of dispute relative to any supposed resemblance between this Journal and that of the Photographic Society, but upon the words of the title only, and this being now happily set at rest, we hope to maintain those relations of amity and goodwill with our elder contemporary that have never been interrupted but upon the one point of difference now removed. May we both enjoy a long career of usefulness.

We find on looking over our summary of the past year's photographic history that we have inadvertently committed an error in attributing to Mr. Heisch the credit due to Mr. Thomas R. Wheeler, the accomplished Secretary to the Blackheath Photographic Society, for testing the value, as a photographic agent, of Dr. Schweitzer's solvent of cellulose, the oxide of cuprammonium. This arose from our having trusted to memory instead of referring, as we should have done, to the papers which have already appeared in our pages, and from having Mr. Heisch's name so familiarly before our mental vision in connexion with other valuable chemical investigations, the results of which have been made public at the meetings of the Blackheath Society. We have to crave Mr. Wheeler's indulgence for our mistake: his labours have been no less valuable than those of Mr. Heisch.

In alluding in our last to M. Poitevin's method of producing direct transmitted positives in the camera, we pointed out the probable value of this process (if found readily practicable) for the purpose of taking out-of-door subjects upon a small scale, and subsequently producing enlarged negatives in the megascopic camera, from which to print our positive proofs. It did not occur to us at the time, that by a slight modification of the proposed arrangements we might accomplish the same end in a still more convenient manner. Besides our present want of familiarity with the manipulation of the process as given by M. Poitevin, and the consequent uncertainty to be anticipated in its use until we become better acquainted with it, there is also the drawback of its requiring a more protracted exposure in the camera, asserted to be three times as long as when using a plate prepared with the same collodion and calculated to produce a negative impression. Now by taking sharp negatives of small dimensions—say, for instance, of the usual stereoscopic size—we might by M. Poitevin's method produce enlarged negatives by one operation direct in the camera; and in this case the increased exposure and chances of failure would be of comparatively little importance. The arrangement we are now proposing is substantially the same as formerly, but there is a slight change in the order of the respective manipulations introduced.

As regards the importance of printing direct from negatives by contact, instead of attempting to do so upon paper from small negatives in the enlarging camera, we were much impressed by a remark made by Mr. Beattie, of Bristol, in a conversation which recently took place between us. This gentleman pointed out that artistic effects are much more under control in the former case, especially as regards the backgrounds of portraits —a proposition we imagine not likely to be called in question.

We have upon several previous occasions drawn attention to the desirability for reform with respect to cameras, which, as generally constructed, are too heavy and clumsy, to say nothing of sundry other defects which most of them are afflicted with. We have recently examined a novelty in cameras of very considerable merit, lately introduced by Mr. A. J. Melhuish, of Blackheath—one which, when first it was named to us, we did not at all anticipate would turn out to be of any great importance, but which we now regard in a very different light. The camera alluded to is constructed of *metal*—viz., brass electro-plated, or german silver; and the inventor contemplates, at no distant day, the probability of constructing it also in *aluminium*. The advantages are portability, rigidity, cleanliness, lightness, compactness, and freedom from the liability of becoming deranged either by heat or moisture. As yet we have only seen cameras adapted for taking stereoscopic negatives constructed upon this principle; but we see no reason why they should not be equally efficacious upon a larger scale. It might be objected that metal is easily bent out of shape—in fact it was one of the first objections that occurred to us; but when we saw how ingeniously this has been guarded against by the peculiar method of framing the structure of the instrument, we could not but admit that any force which would bend the metal would break the wood. The weight is not greater than a corresponding wooden camera, and if made of german silver we believe it would certainly be lighter, while in the event of aluminium being employed it would unquestionably be *considerably* lighter. Metal, though a good conductor of heat, when polished, effectually reflects it instead of absorbing it, unless exposed for a considerable length of time to the direct rays of the sun; and a piece of yellow velvet thrown over it when in use would, if needful, obviate that inconvenience.

Besides the material employed for its construction, there are several ingenious and useful novelties applied; for instance, although the dark frames are introduced at the top, in the usual manner, the sliding doors to them open *downwards*, thus totally avoiding the possible ingress of light, and at the same time removing the too frequent cause of tremor when operating under the influence of a summer breeze. The compactness, too, of the instrument is something quite refreshing after the numerous clumsy contrivances that we so constantly meet with. The camera, which is scarcely half an inch each way larger than the dimen-

sions of the glass plates to be exposed in it, *itself* acts as the receptacle for six double backs containing twelve plates, one single back for wet plates, and the focussing screen. Ingenious little metallic strap-like handles enable the operator to draw out the backs and slides with the greatest ease, while they are so contrived that, when not in action, they lie flat against the instrument. The whole affair (lenses and all), when not in use, is packed into a convenient leather case, with a strap, enabling the photographer to carry it readily in his hand or to sling it across his shoulders as he would a telescope.

Mr. Melhuish has also constructed a very excellent folding tripod, which we much admire. We had ourself contrived an arrangement of this nature, which we have had in use for the last twelve months, and which we find extremely handy and pleasant to use, but we prefer Mr. Melhuish's to our own in some respects. We are convinced that these pieces of apparatus will be hailed by many photographers with pleasure.

For the benefit of our numerous readers at a distance from the metropolis we annex illustrations of this ingenious camera. Fig. 1 as it appears in use. Fig. 2 packed in leather case.

FIG. 1.

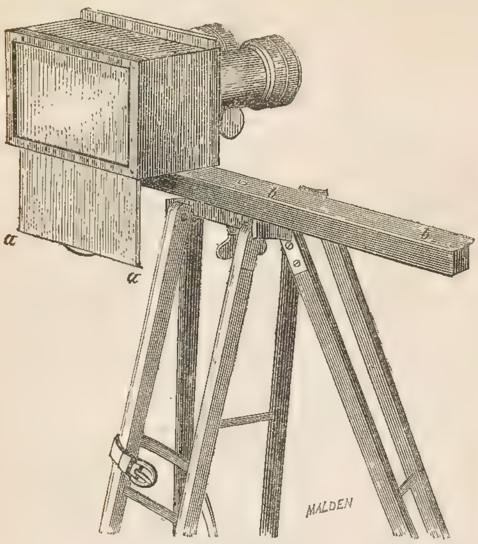

FIG. 2.

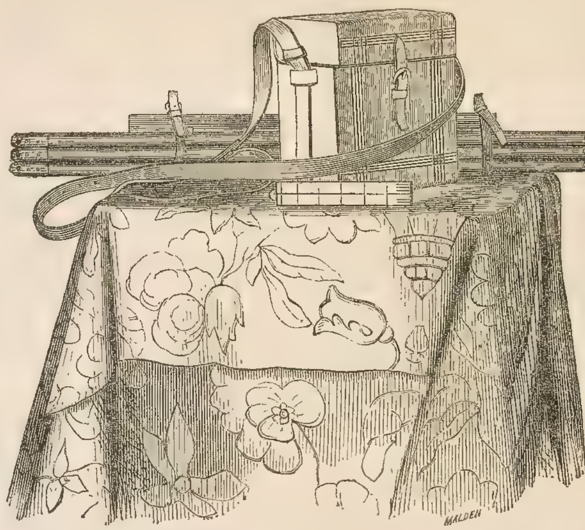

ON THE FOCUS OF LENSES.

We have received a note from Mr. M. Noton, of Manchester, kindly drawing our attention to the fact, that the relative proportion between the conjugate foci of lenses which we had imagined to have been first propounded by Mr. Claudet has been long known to those familiar with Smith's *Optics*, and other works, in which an extract, with illustrative diagram therefrom, has appeared. As we had never met with the illustration in question we were previously unaware of its existence.

In consequence of the preceding intimation, we were led to examine more closely the remaining details of our article, and on doing so, perceived that one of the methods we had given for finding the principal focus of a combination, though suitable where the components are *in contact*, does not hold *strictly* true when they are *more or less separated* — because, supposing the components to be of equal power, an object placed in the solar focus of the anterior lens, for instance, will transmit the rays *parallel* to one another, and these falling *parallel* on the other lens, will be united in *its* principal focus; hence the apparent focus of the whole combination would by the rule given be a trifle too long. As we have no object but to afford reliable information, we at once correct the error into which we had by our haste inadvertently fallen.

Since writing the above we have received the following on the same subject, which puts the affair on a still simpler footing:—

"Dear Sir,

"The apparently curious relation, alluded to in your last number, as existing in the conjugate foci of a lens has been recognised at least as long as Dr. Smith's *Optics* (now an old work) has been in being. It has also been copied into several subsequent optical treatises, and has, therefore, no pretension to being a new discovery.

"Nor is it as useful as a much simpler and obvious one. It has always appeared to me that the rule as handed down to the present had been constructed more with a view of putting a *striking* than a simple or convenient ratio before us. The distances (as you have observed) are not taken (or to be measured) from the lens, but from a certain empirical distance (once the principal focus) at either side of the same, consequently we have to add this to each side of the ratio before we can make a practical use of it, and *then* the previous ratio (except in a solitary instance) *no longer exists*.

"To illustrate this, I take from a table constructed in accordance with the rule, four ratios, which for reference sake are entitled a, b, c, d.

a	1 f and 1 f
b	2 f and $\frac{1}{2}$ f
c	3 f and $\frac{1}{3}$ f
d	4 f and $\frac{1}{4}$ f

'f' in the table denoting the principal focus of the lens or feet when the focus is = 1 foot.

"I think it must be conceded that there is nothing in this table to indicate directly any ratio required except that of 1 to 1; and I therefore propose to adopt in preference the more simple and natural ratios of the actual distances from the lens, which, although not as striking perhaps to look at, will be found much more convenient and simple in use; for example:—

a	2 f and 2 f
b	3 f and $\frac{3}{2}$ f
c	4 f and $\frac{4}{3}$ f
d	5 f and $\frac{5}{4}$ f

"In this table the proportions required are at once apparent, while the numbers denote the actual distances required to be used for a focus of 1 foot — the ratio being still of so simple a progressive nature that a table of any required extent can be constructed almost as quickly as the figures can be written.

"Lastly.—The rule by which the foregoing table is constructed admits of the most clear and satisfactory proof by comparison with an exceedingly simple algebraic formula.

"Let it be borne in mind, first—That 'f' represents the focus of the lens, and that this focus is assumed to be =1 foot, or unity; and secondly, that we do not alter the *power* of a lens by using it, whether for bringing parallel rays to a focus or for forming conjugate foci. What we do in the latter case is simply to use a portion of its power on one side, leaving the *balance* of its power to be exerted on the other side — the simplest case of this being that where we use the lens for forming *equal* conjugate foci, and where, the lens being one foot in principal focus, a power equivalent to a focus of two feet is used at one side, leaving an equal power to be exerted at the other side. Now it requires very little mathematical knowledge to perceive that we can only perform the operations of adding and subtracting such powers by treating them *as fractions*—that is by using their *reciprocals*; and thus, as we express the adding of two halfpennies, viz.,

$$\frac{1}{2} + \frac{1}{2} = {}^{1} = 1 \text{ penny},$$

we, in like manner, must, in adding the two before-mentioned powers of two feet each in focus, adapt the formula (p and p^1 being put for the respective powers): —

$$\frac{1}{p} + \frac{1}{p^1} = \frac{1}{f} \text{ (and p and } p^1 \text{ being each} = 2 \text{ feet.)}$$

$$\frac{1}{2} + \frac{1}{2} = \frac{1}{1} \text{ or focus} = 1.$$

From this simple equation we gather that (calling the whole power of the lens 1 or unity) then the sum of the reciprocals of the powers (which are at same time the required distances from the lens) *must equal unity;* or in language less mathematical, any two fractions whose sum is unity will, in their reciprocals, give relative distances of the object and image for a lens whose principal focus is 1, foot, yard, &c.

"And the general arithmetic rule deducible from this, for finding the required distances FOR ANY PROPORTIONAL SIZE OF OBJECT AND IMAGE, AND FOR ANY GIVEN FOCUS OF LENS, is —

"*Add the required proportions together for the denominator of two fractions, whose numerators are the* SEPARATE *numbers. Invert these fractions, and multiply the focus of the lens by each of these for the respective distances.*

"The following examples will suffice. The first of them is taken from the table already given: —

Proportion of conjugate foci 1 to 4 (focus 1.)
$1 + 4 = 5$ for the denominator.
$\frac{1}{5}$ and $\frac{4}{5}$, the fractions.
$\frac{5}{1}$ and $\frac{5}{4}$, the fractions inverted.
$= 5$ and $1\frac{1}{4}$, or 5 and 5-4th, as per table.

"Second example: —

"Assuming the required proportion to be as 5 to 6, and the focus of lens to be 15 inches —

$5 + 6 = 11$, the denominators.
$\frac{5}{11}$ and $\frac{6}{11}$, the fractions.
$\frac{11}{5}$ and $\frac{11}{6}$, the same inverted.
And these multiplied each by 15, give 33 inches and $27\frac{1}{2}$ inches for the relative distances.

"The foregoing I apprehend to be as simple a method as can be devised for ascertaining the conjugate foci in every case. I have endeavoured to render not only the rule but also the principles on which it depends intelligible to all readers. The rule is however strictly correct only for a single lens or combination. You will perhaps, before receiving this, have observed that where a combination of lenses *with intervals between* (such as the portrait combination) is to be used a correction (or allowance) will have to be made, and that consequently the rule you have given is not for such cases strictly correct, though it may be sufficiently near for ordinary practical use. I hope in another letter to touch upon this second portion of the subject.

THOMAS GRUBB, M.R.I.A.

Dublin, December 21, 1859.

PRACTICAL OBSERVATIONS UPON PHOTOGRAPHS IN THEIR RELATION TO ART.

By ALFRED H. WALL.

[Read at the Meeting of the South London Photographic Society, December 15, 1859.]

BEFORE commencing this paper I pondered carefully upon the character I should (or could) give it: practical I had determined it should be, useful I hoped it would prove, and yet it absolutely needed an introduction which in itself would constitute a long communication. I must, therefore, solicit your indulgent consideration.

Whenever I take up modern works upon, or connected with, Art, I find that however much they may disagree in regard to various Art questions of the day, they are generally harmonious in asserting that photographs are "not works of art:" to look upon them as such, says the *National Magazine*, is "a common and ungenerous mistake." Mr. Frank Howard (a gentleman well known as a writer and lecturer upon Art), in the 13th number of the *Journal of the Photographic Society*, pooh poohs the idea of photography rivalling even the humblest branch of art, and, in a sneering spirit, brings prominently forward, and makes the most of, every defect in its productions. A very eloquent and well-written article in the *Quarterly Review* (which is frequently quoted) makes much of all its weak points, also; and in the *Art Journal* for December, 1858, a "dialogue held in an artist's studio" appeared under the title of "photography for portraits," which displayed no little feeling against the new art. You may, perhaps, remember that this dialogue takes place between an artist of the ideal school (so much talked of and so little understood) and a certain vulgar, illiterate, and be-fogged nigger overseer, named, expressively enough, "Dogberry," who, visiting an artist's studio in a great hurry to get his portrait "taken off," naturally stops a tediously long time to smoke a cigar and conduct a long argument with the artist in favour of "photography for portraits." As the artist is a talented, educated, and dreadfully refined individual, and Mr. Dogberry a conceited imbecile, with profound contempt for music, poetry, and painting, but admiring photography and *cheap coloured lithographs*, the aforesaid argument is, of course, by no means one-sided, and everybody wonders at the glorious victory achieved by the representative of Art over his self-created opponent. I might refer to no end of other similar attacks (emanating in many instances from disappointed fifth-rate painters), but it is no part of my present purpose to refute their objections.

If we desire to know why photography is thus disparaged, the reason is so plainly visible, that — putting aside "envy, jealousy, and all uncharitableness" — we have but to look around and see it.

In the first place, among the many thousands of photographs passing before us, how many are there which have the slightest claim to any pictorial element? Alas, the number of these is so sadly small, and photographs have, in a general way, so little pretension to any thing approximating to Art, that we cannot but regard any want of permanence, which most of them may display, as a charitable arrangement of Providence, brought about by the Genii presiding over the beautiful and true. The ease and facility with which a little may be done in photography are its worst foes, and fill our streets with hideous representations of humanity, our folios with drearily uninteresting specimens of snowy or sooty landscapes, and our shop-windows with disgustingly indecent or tawdry theatrical groups, under deceptive titles.

In the next place, as a body, photographers have not set up their standard sufficiently high: great as the superiority of the productions of to-day may be when compared with those of a few years back, in one vital point they are the same — they have no greater claim to artistic qualities. The reason of this may be found, not in photography, but in its students and professors, who take up the art as a mere amusement, a mere mercantile speculation, or as a purely chemical or optical study, without supposing that, as a branch of Art, all the principles of pictorial science are essential to its successful practice. Look at the oldest of our photographic societies, the members of which may surely be supposed to have passed the simply rudimental portion of their art: their studies are still confined to manipulating details; and of all the papers read and discussed at their meetings how few of them have a tendency to increase their conception and appreciation of even the elementary studies of pictorial art! Compare the art-student with the photographic: the first, educated to his profession from early youth, giving years of labour for elementary knowledge, and making every various phase of his progress a subject of earnest study; the other, purchasing his apparatus to-day, and in a few months producing pictures which, being sharp, clean, and well exposed and well developed, seem to him the legitimate *end* of all his efforts. Again, take up the various representatives of photographic literature and compare them with those connected with Art. The first is devoted almost entirely to the mechanism of photography — baths, processes, and modifications of processes, trivial improvements in apparatus, tents, lenses, cameras, and, sometimes, I regret to add, to bickerings and trivial disputes neither dignified nor estimable. The art-publication, on the contrary, gives pre-eminence to scientific principles, enforces rules founded upon the experience of great painters, and the inductive reasoning of great thinkers; the vital importance of which are demonstrated by the productions of the first, the conclusions of the latter, and the instinctive recognition of the uneducated eye.

In making these few remarks I trust I shall not be misunderstood. The mechanism of any art is of great importance, and more particularly is it so in photography; but it should be considered *the means* and not *the end.* The Photographic Journals are invaluable as aids to progress, and we all owe them a deep debt of gratitude; but they should aspire to something above the mere mechanical: their great power should be the chief means of raising our beautiful art to its well deserved niche in the grand domain of Art. But for all the errors I here venture to denounce, photographers alone are responsible; *their* works create erroneous impressions on the public mind, and *their* writings fill the pages of our literary representatives. But our art is young, and has—like other young folk—much to learn.

With these few necessary remarks by way of introduction, I will, without ignoring the existence of serious optical and chemical difficulties, now take my ground, in opposition to the Frank Howard and Ronald Campbell school of reasoners, by asserting that light plays much the same part in photography that pencils do in drawing, and that photographs are the production of the camera in exactly the same sense as paintings are the production of paint; that bad photographs, however numerous they may be, are not more

legitimate arguments against photography than bad paintings are against painting. Being both artist and photographer, my evidence may perhaps be received with less suspicion than it would provoke if it emanated from the first or the last only.

I propose, then, to throw together a few practical suggestions upon composition, the management of light and shade, &c., in their application to photography.

I do not think that our most ambitious branch of photography, viz., that which takes the same relative position as historical painting does to Art, can ever attain a permanent standing; for in historical painting the grand aim is not to represent things in actual existence as they really are, but rather to select the scattered fragments of expression, or beauty, and blend them into one harmonious whole. I shall presently show some specimens to illustrate this point. The legitimate compartments of photography are to be found in groupings illustrative of various incidents—in landscapes and sea views—in studies from the nude, from cattle, and from objects of various kinds—in portraiture—in representations of still life (such as that true *artist*-photographer, Lake Price, has produced)—and in architecture. Surely here is field enough for our labours without hopelessly rivalling unconquerable giants so high above our pigmy efforts!

Of course I can now merely make a *very few brief remarks* upon each of these branches—mere indication of things claiming more important treatment.

In grouping figures to illustrate various incidents, the chief element of success lies in the choice of clever models; and, most decidedly, for mere physical characteristics, we shall find our best subjects in the studios of artists: but for facial expression they will be found almost useless; for this our best models must be sought among men and women whose minds are imbued by nature or cultivation with poetical conceptions, who, feeling deeply, will express correctly the various passions or sentiments required. And here comes the most serious difficulty—poetically organised beings are not frequently found among the class of people who would sit to an artist as a model. Occasionally we meet them. I remember seeing a young gentleman of the shoe-black brigade, who was narrating, to a suspiciously ragged and dirty young urchin, some terrible story, and so full of horror was the one boy's face, and so absorbing was the open-mouthed attention inscribed legibly upon the other's, that I stopped, and found that the brigade boy was simply explaining a passage (in his own emphatic but not very elegant or grammatical language) from some romance of blood, bogy, and blue-fire school. Now, here was, I doubt not, one who might have been trained into a most excellent model: his features were capable of expressing strongly emotions which he was evidently susceptible of feeling deeply, and these are exactly the qualities needed for a photagrapher's model. In most of the photographs of this class which I have seen the models have evidently been chosen for their outside appearance rather than for their capability of expression. Models from the stage are very seldom of use, being of the stage, stagey. I would therefore advise the photographer who takes up this department to cultivate his conception of the picturesque, and look about him for models in the almost unexplored scenes of humble life. In depicting passions we must be careful that by exaggerated expression we do not, as *Hamlet* says, "tear a passion to tatters," nor "overstep the modesty of nature." Refinement must never be lost sight of in every production of art. To *succeed* in this branch undoubtedly requires the education of an artist. Attention must be particularly directed to the study of expression, in order to select that which is most natural, effective, and true to a purpose. Composition imperatively craves *some* study: in groups, crowding must be avoided; ungraceful angles in limbs or accessories shunned; the laws of proportion and symmetry studied. Drawings, paintings, and statuary (especially the antique) should be carefully observed for a perception of the beautiful, and an eye educated to discover it must be arduously sought. The artist should also remember that expression is not confined to the face, but speaks in every motion of the body and limbs, and that certain forms and faces have in themselves poetical expression apart from muscular motion altogether. Variety must not be lost sight of, nor contrast neglected; unity of purpose and the relative subserviency of parts must be attained; breadth preserved, &c. But I must quit this subject (which is indeed a vast one, and in itself sufficient for several long papers), and content myself by simply adding that much may be done for the picture in the printing and development, or when several negatives are used, by varying the exposure in the camera, so as to obtain more definition and relief by stronger tones of light and shade in one portion than another, &c., &c.

Landscapes next demand a few practical hints. In this branch, and that of portraiture, photography has progressed most rapidly.

The choice of light is of primary importance in taking a landscape. If the light be immediately before your camera, the objects in the same position must necessarily be in shadow, which may sometimes greatly aid you (if desirable) in procuring a mass of halftone. A specimen I have brought down, in which the sun has evidently been looking *into the mouth of the lens*, will serve to illustrate this; but another I have will serve to show its general ill consequences. If the sun be immediately behind your camera, there will, generally, be a want of shadow and force of effect. [A specimen illustrative of this was shown.] The position best liked by painters is that in which the light comes from either the right or the left, as we have then strong contrasts of light and dark, unity of half-tints, and powerful relief; but much must, of course, depend upon the character of your view, as even this light in some exceptional cases, might produce a spotty effect destructive of breadth. [Several fine specimens, by Mr. F. Howard and others, were handed round.] Beyond a doubt the most *brilliant* pictures are obtained near mid-day; for both lights and shadows are then most intense, and the exposure is shorter; but photographs so obtained are seldom (I think) very *artistic*. Nearer morning or evening, when the lengthening shadows blend into masses and the lights are not so strong as to be destructive of harmony (in the gradations of tone), will be the best time for an artist-photographer. As some portions of the view must necessarily receive the most light, it would be as well, perhaps, if you could so contrive that the strongest light should be found upon the foliage. The faults I most commonly meet with, in otherwise good photographic landscapes, are a want of shadow and a want of contrast, arising, in many cases, I doubt not, from the operator's almost instinctive dread of the strong lights and darks of nature resulting in a "soot and whitewash" effect in his picture. I think I have brought down sufficient proof, in the specimens I shall now show, of the exaggerated nature of this fear. The stops used in lenses are so various and important in their effect, that you must permit me to advise our beginners to try some few experiments in this direction, if they have not already done so. I am inclined to think too small a stop disadvantageous. Long exposure may destroy some force of effect in the more minute details of the lights; but this is more than compensated for by the greater transparency, detail, and purity obtained in the shadows. Here again, gentlemen, we meet with demands beyond that of the mechanical: here the taste and artistic knowledge of the photographer will surely be of greater service than his manipulatory and chemical skill; for the last is useless without the first. When he takes out his apparatus, he has not only to choose his scene with reference to light and shade, as related to pictorial effect, but, to produce really *artistic* pictures, he must also study the *chiaroscuro* with reference to the peculiar character of the chosen subject, inasmuch as his pictures are, apart from colour, as capable of conveying sentiment as a painter's. This is a fact too commonly overlooked. The mere representation seems nearly always to bound a photographer's aim (and thus it is that there is a strong impression on the public mind that the photographer's occupation is, after all, worthy only of being classed among the mere handicrafts). For instance, gladness abounds in the brilliancy of sunshine; placidness and peace speak most eloquently in the harmonious blending of subdued tones; and a general gloom, with intense black shadows, has a grandly powerful voice when associated with the rugged and the desolate. In printing your picture, its colour may also tend greatly to enhance the sentiment and general effect. I must not dwell longer upon this, however, but content myself by adding that taste, elegance, and expression should characterise all your productions.

Barnard, in his excellent work upon Landscape Painting, while praising photographic landscapes for their perfect representation of tints and shades, says:—"It must however be confessed that, even in the most perfect of these philosophical productions, a certain amount of pictorial effect is wanting, and a deficiency is felt of that concentration of interest caused by a more artistic application of the laws of *chiaroscuro*." This is unfortunately but too true.

Another element of the picturesque has been greatly neglected by the photographer, viz., atmospheric effects.

I do think there never was a greater blunder made than that of destroying the aërial perspective of the extreme distance by obtaining the hard line of a cut-out horizon, and the glaringly prominent truth-and-beauty-destroying absurdity of *a white paper sky*. If we *must* have clean skies, and *will* sacrifice atmosphere and per-

spective to obtain them, why on earth need they be *white?* Are we not able to graduate them with the greatest ease from a gleam of light near the horizon, upwards, into a tone of any depth? Or, better still, cannot we take a second negative of the identical sky spread above our view, and by double printing give our picture an amount of perfection which otherwise it can never claim? The hard horizontal line would even then remain, but it might at least be modified by the aid of a little wool or silver-paper in the printing process.

The effect of atmosphere is also too little appreciated in photographing distance, although it is the most enchantingly-picturesque of all mediums, lending that soft dreamlike obscurity to the fading objects as they dwindle and recede into air, which is most poetically expressive of all the charms of ever-varying nature. Clear, brilliant days for distant landscapes may give that wondrous diversity of detail and distinctness which charms the uneducated eye; but, after all, a mass has similar qualities in much greater perfection, without being either very picturesque or strikingly beautiful. Partially-condensed vapours, or the semi-transparent gleams of partial sunlight are in themselves fruitful sources of effects which rouse the artist into a fervour of admiration and a fever of ambitious anxiety. Many suppose that such beauties defy our art; but I have seen many photographs in which their glorious effects have been very faithfully rendered. You may perhaps remember a stereograph called *The Rising Mist*, published some time since. I hoped I should have produced this and others illustrative of atmospheric perspective, with some which I shall presently send round. [Wilson's sunsets and other photographs were here shown.]

Not to dwell longer upon landscape photography (as my motive is rather to call the attention of members to the wide field open to them for study, and the many subjects upon which it is desirable we should have good papers, than to give to any one of these matters that attention and time which they justly demand), I will now conclude with a few observations upon portraiture.

The remarks made upon grouping will apply with equal force here.

The position of a sitter should be such as will display the greatest variety of graceful undulating lines, or be the most characteristic of the individual.

The head should represent the principal light, and minor lights should graduate from it, as a focus, to the deepest shadows. The effect will derive great force from the judicious introduction of a spot or focus of intense darkness somewhat near the highest light; of course this so-called "spot" must not offend probability, nor destroy harmony.

Photographers are not, as a whole, aware of the great importance to be attached to the preservation of pure whites. If we consider that the lights and shadows of nature range from the intense brilliancy of white light to the absolute darkness of a nearly total deprivation of light — while a photograph can only represent this vast scale by the few tones graduating from white paper (generally seen in a subdued light) to shadows certainly not black, being considerably lighter, as a surface reflecting light — we shall then see how important it is that we should not lessen our scale of tones by substituting grey for white. I do not know a better illustration of this than is to be found in the alabastrine process. Take an ordinary positive with its so-called whites of a light leaden hue — more or less — and whiten it with the alabastrine or bichloride solution, when you will discover that, as the picture whitens, its scale of tones seem suddenly to grow softer and more delicate, and its contours much rounder and more forcible; an effect to be traced solely to the introduction of pure white and the intensifying of the deeper shadows, or, in other words, is in the increased compass of the scale of semitones.

The general faults in most photographic portraits are the absence of reflected light — the over-exposure of the face, to bring out the details of drapery — and (I know I am about to propound heresy) the terrible sharpness of their definition, which I never can reconcile with binocular vision. (I do not recognise the thousand and one cheap abominations in our streets as photographs at all, so must not be considered as referring to such singular productions the general faults of which would alone demand a longer paper.) In illuminating the sitter, the light should enter at an angle of not less than 45 degrees. The amount of direct light should be small, and to give delicacy, transparency, and truth to the shadows, light should be reflected from white screens placed upon the shadowed side of the figure. The object to which you direct your sitter's attention should be dark, as it is less fatiguing to the eye than a light one would be, and also (by enlarging the pupil) improves its expression. Be careful to avoid so placing your white screens as to reflect a glare of white upon the eye. In giving ease to the pose do not carry it into affectation, which is as great a fault as awkwardness and clownishness. The background should spread the light and aid in securing breadth. A very capital one is made by painting it with colour containing more turpentine than oil, and afterwards stippling in, or near, the centre, with the end of a large brush, a colour considerably lighter, graduating it from a centre into the colour first applied.

I must now conclude. In pointing out a new field for our studies, and dwelling upon its importance, I hope, gentlemen, you will assist me in bringing forward papers of *an artistic character*, which, blending with the amount of practical, manipulative, and chemical experience which we already possess, will tend to raise the art we all love high above the sneers and ill-natured attacks of a class of dreaming idealists, who would fain make an artist one of the most mysterious of the world's creations, and his productions things to be viewed with unquestioning faith and superstitious reverence. The cause of Art is at enmity with these worthies.

By way of illustrating my remarks I must refer you to some of the specimens before you.

In the series illustrative of Little Red Riding Hood's tragic story the various expressions on the face of the child will show what a good model can do, as will also that on the face of the female model from Rejlander's *Seven Ages*, and those found on the faces in *The Scripture Reader*, *The Wayfarer*, Robinson's picture called *I know*, and in *Mariana*.

For characteristic effect of light and shade and the expression of sentiment I must refer you to *The Convent Bell*, *The Five Foolish Virgins*, *The Spinning Wheel*, more particularly that with the dark background, *The Abbey Gate in Yorkshire*, by F. Bedford, some stereographs of Rochester Castle and other spots, by our Treasurer, *Guy's Cliff*, Watson's *Roman Bridge*, *The Wayfarer*, and *Tong Village*, by Rejlander.

For atmospheric effects I must refer to the three slides of Wilson's from Aberdeen representing sunsets. These will also serve to show how singularly important a sky is to the picturesque. For instances of the destructive influence exercised by white skies take — *all pictures which have them*, more particularly an exquisite vignette of *Blackburn Priory*, by Delamotte (so sadly spoilt), and *Conway Castle*, by Rosling.

For "breadth" refer to the *Abbey Gate*, by Bedford, one of the most beautiful and artistic photographs in the volume before you — to the third picture of the *Red Riding Hood* series — to the pictures called *The Spinning Wheel*, *The Scripture Reader*, and *The Convent Bell*. Not to delay the discussion, which I hope will follow, I thank you for a patient hearing, and conclude.

THE PATENT METAL CAMERA.

By A. J. Melhuish.

[Read at the North London Photographic Asociation, December 28, 1859.]

I have been requested to call your attention this evening to a camera that I have constructed, which appears to me, and I think I may say to all who have seen it, to possess very considerable advantages over the ones now in use.

Before, however, proceeding to do so, it may be well to consider the conditions required to constitute a really perfect photographic camera; for by so doing we shall the more readily perceive how near each claimant approaches or how far he falls short of the desired standard of excellence.

A photographic camera to be perfect should be made of such *material* as will never, under any circumstances, be affected by change of climate, heat, or moisture — of such material as will neither affect or be affected by the sensitive plates, but will rather preserve them as long as possible, and of that material (if such can be found) which combines with the least weight the greatest strength,

It should be so *constructed* that by no possibility can the light ever reach the sensitive plate — that the shutting of the slide may be withdrawn without disturbing the focus — that it shall occupy the smallest possible space, and be carried as it is used (I mean without taking to pieces) — and last, but perhaps not least, it must be moderate in price.

Now, gentlemen, if I show you a camera which fulfils to the letter all these conditions, I think I may flatter myself that the term so often misapplied may be in this case justly claimed, and that all will concur in acknowledging it to be the *ne plus ultra* of photographic cameras.

We will now run through the various points separately. "A photographic camera should be made of such *material* as can never,

under any circumstances, be affected by change of climate, heat, or moisture." That this condition is fulfilled by a metal camera and is not by a wooden one need not be urged, but is self-evident.

"Of such material as will neither affect nor be affected by the sensitive plates, but rather preserve them as long as possible." The wet collodion slide of my camera being electroplated with silver within and without can "neither affect nor be affected by" the wet plate; whereas with the wooden ones they generally stain the plate more or less, and the plates gradually spoil the slide. Moreover, I think it highly probable that the wet plate which so soon spoils and dries in a wooden slide may be kept in my metal one, which absorbs no moisture and is nearly air-tight, a very considerable time.

"And of that material which combines with the least weight the greatest strength." The new metal camera is constructed of sheet metal so thin and so strengthened by frames of the same that I find that, when made equal in strength to the wooden ones now in use, it is about one-third lighter, and when made of equal weight it is at least double the strength. Should the metal camera have a severe fall it would be bent, and would require to be straightened; should a wooden one meet the same accident it would probably be broken.

"It should be so *constructed* that by no possibility can the light ever reach the sensitive plate, and that the shutter of the slide may be withdrawn without disturbing the focus." The shutter of the dark sliders now in use draws up or on one side; consequently, as all are aware, it is very difficult in full sunshine to prevent the light reaching the plate while opening and shutting the slide. The shutter of the metal camera glides smoothly down without disturbing the most delicately-adjusted focus, thus rendering it impossible for the light by "any possibility" to reach the plate during any length of exposure.

"That it should occupy the smallest possible space, and be carried as it is used." Here all comparison with anything yet made will appear needless when I say that my metal stereoscopic camera, with six double dry plate slides (containing, of course, twelve plates), one wet collodion slide, and focussing frame, occupies less space than an ordinary twelve-groove plate-box. It is carried as it is used.

In conclusion, I think I ought to add that I do not claim to be the inventor of metal cameras. That honour, I believe, falls to M. Voigtlander, of Vienna. Mr. Skaife, too, of Blackheath, has lately constructed a very ingenious little instrument, which, were it moderate in price, would, I think, be much used. He calls it "the pistolgraph" — by means of which he takes "*chromo-crystal pistolgraphs.*" Like Voigtlander's camera, it is made of metal tubes.

But I think, gentlemen, I *may* claim to be the first who has made a metal camera where its many and manifest advantages over wood are not nullified for ordinary use by the singular and inconvenient method of its construction — to be the first who has made a metal camera of *practical* value for general use.

ILLUSTRATED DESCRIPTION OF MESSRS. SMITH, BECK, AND BECK'S PATENT ACHROMATIC MIRROR STEREOSCOPE.

WE recently described in our pages* the excellent hand-stereoscope indicated above, as well as we were able to do so without woodcuts; we have now to present to our readers an accurate illustration of the instrument, with description in the inventor's own words:—

We have contrived this Instrument expressly for the exhibition of paper stereographs, either as mounted in the ordinary way, or, as there is every probability, they will frequently appear as illustrations in books. The principal feature of this stereoscope is the application of a mirror in such a position as that, when the instrument is held facing the light, the picture receives reflected rays, in addition to the direct ones: this double illumination not only imparts a proportionate brilliancy to the photographs, but, from the circumstance of the light falling in opposite directions, there are no shadows to the irregularities upon the surface of the paper, and thus many of these annoying imperfections are rendered invisible.

We have also combined with this arrangement the same achromatic lenses as in our other stereoscope, so as to afford the best definition, and to correct the colour produced on the margins of objects by single lenses. The adjustments for different kinds of vision, as hereafter described, are as complete as possible; and a ground-glass division, which separates the pictures without under any circumstance throwing a shadow, as well as the brass frame, which forms a margin to the object, will both be found of essential service.

SMITH, BECK, & BECK.

DIRECTIONS FOR USE.

The instrument is intended to be held in the left hand by the handle A, and facing the light, the right hand is then at liberty either to shift the views, or to make the necessary adjustments

The milled head B is for the adjustment of the focus, by rack and pinion. Those who have "long sight" will require the lenses farther from the picture; and as the full extent of the rackwork is frequently not sufficient, the distance can be increased by drawing out the lenses in their fittings at C C; the reverse is, of course, required for short sight; whilst many of those whose vision is unaffected in either of these ways will be able to see well through the whole range of adjustment.

Every stereoscopic slide consists of two pictures, but they must unite and form one in the instrument. This will generally be the case when the two arrows on the brass rings D D point to each other; but there are some kinds of vision and, occasionally, errors in the slides, which require one or other of the lenses to be slightly turned round in its fitting C. The method of mounting admits of this, and also of their being easily taken out for the purpose of wiping, which should be done frequently.

The slides are placed under the brass frame H, and under the springs E; but if the stereograph is in a book, the springs are turned up, as shown in front view.

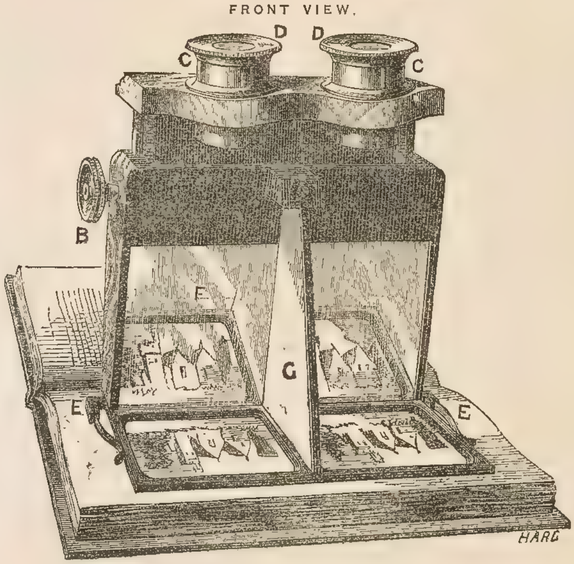
FRONT VIEW.



NOTICES OF RECENTLY PUBLISHED STEREOGRAPHS.

SCOTTISH GEMS.

IN a recent number* we had much pleasure in noticing some very beautiful results obtained by Mr. George W. Wilson, of Aberdeen, in the production of a series of stereographic photographs, in which some highly artistic effects, hitherto unattained by aid of the camera (so far as we are aware), had been accomplished. These were indeed so much out of the ordinary class of stereographs, both as regards execution and subject, that we felt it necessary to criticise them rather as photographic contributions to art, than in our usual manner. At the close of our notice we intimated that there were others which we had to describe under our usual heading, but before proceeding to do so, we may remark, for the information of our readers, that the whole of Mr. Wilson's negatives were taken

* Vol. VI., page 294.

by the moist collodion process, and developed with the protosulphate of iron.

We shall begin with two subjects corresponding to some criticised very recently in these pages, that were taken by Mr. Archibald Burns, of Edinburgh, by the Fothergill process. They are —

The West Door, Elgin Cathedral.—This differs so little from the specimen by Mr. Burns, both as regards the amount of subject included and point of view, that it is really surprising, especially when we know that they were taken at a considerable interval of time between the two. In Mr. Wilson's specimen the spectator is a trifle more towards the right hand side, and the sun was shining when the negative was taken; there is also a figure seated upon the steps leading up to the doorway, and two others are visible in the interior of the ruin. Mr. Burns's negative, on the contrary, must have been taken in cloudy weather, and it is destitute of figures. In all other respects there is no more difference perceptible between them than the usual individuality with which skilled operators invariably impress their works.

South Door of Roslin Chapel.—Mr. Wilson's copy of this subject is taken upon a larger scale than that of Mr. Burns, and consequently less of it is included. The upper windows which form so remarkable a feature in Mr. Burns's, are wanting in Mr. Wilson's copy, but this absence is fully compensated by the increased beauty of the effect of the open doorway, in the embrasure of which a lady is standing, as if about to enter. At the opposite side of the building another door is open, at which there is a gentleman looking in, while still further off is a third open door, through which is seen a row of garden railings, and a portion of the hedge. Of the two windows visible, many of the squares of glass are wanting, and the larger scale upon which it is taken permits of a better examination of the beautiful carved-work with which the structure is adorned. Both of these specimens are in their way masterpieces of art, and we should not like to part with either of them.

We have made mention of these two subjects at the outset, because we were anxious to point out a fact that we think has been fairly proved by a comparison of the respective specimens, viz., that there is nothing inherent in the dry process that should prevent its rivalling the moist one as regards capability of rendering all subjects in a state of repose; but, for the introduction of living subjects, the wet process has a considerable advantage. We think it but right to mention that though Mr. Burns's representation of Roslin Chapel is remarkably graphic and effective, the delicacy and softness of Mr. Wilson's rendering, together with the introduction of the figures, causes his specimen of this subject to be more of a finished picture.

The Interior of Roslin Chapel is one of those beautiful illustrations that the archæologist will delight in. The massive pillars, one of which is known as the "Apprentice's Pillar," seem but barely able to support the capitals and heavy architraves literally loaded with ornamentation of the most florid character. A gleam of sunshine falling on a huge square block of stone glorifies it; and the general harmony of light and shade, combined with breadth and detail, unite to constitute this a perfect picture which the eye never wearies of gazing on, and which, while we gaze, communicates a sensation of satisfaction and repose that is truly soothing.

The Tomb of Sir Walter Scott, Dryburgh Abbey, is an artistically composed illustration of a somewhat ordinary subject, if we except the associations connected with the name. The tomb itself is barely visible; but a portion of the Abbey, under the shelter of which it rests, is seen through a vista consisting of a buttress or other piece of masonry crowned with the straggling boughs of some creeper on the one side, whilst on the other the squamous stem and lower branches of a stately cedar tree complete the balance. In the foreground are several very ancient monuments, and against the railings a figure is leaning contemplating the last resting-place of one of Scotland's most noted sons.

Balmoral Castle from the S.E. (No. 131) needs no recommendation to render it popular. The favourite residence of our beloved Queen would always excite an interest in every British breast, even if it were represented with less perfection than the specimen before us, which, like all Mr. Wilson's productions, is a model of neatness and perfect workmanship. Apart from the association annexed to it, however, it is perhaps one of the least attractive of this gentleman's subjects, in consequence of its inferiority as regards the picturesque, the edifice being too trim and in too good condition to render it a desirable object for an artist. There is a gardener in the foreground guiding a huge mowing machine, drawn by a plump white cart-horse, led by a second man; the grass, however, is rather too dark in tone to appear quite natural, a defect no doubt arising from its colour.

(To be concluded in our next).

THE POSITIVE COLLODION PROCESS, WITH SOME REMARKS ON THE ALABASTRINE PROCESS.

By G. Wharton Simpson.

(Continued from Vol. VI., page 314.)

THE NITRATE BATH.

This, as I have already said, I prefer sufficiently rich in silver to give a creamy film — about thirty-five grains of pure recrystallised nitrate of silver to the ounce of distilled water. A simple and efficient mode of charging with the iodide of silver is to coat a large plate with iodised collodion and leave it for a few hours in the bath. If on trial a clean bright picture free from streaks or fog be produced, the bath does not require further preparation. This, however, rarely happens. The addition of a quarter of minim to one minim of nitric acid is generally required. I usually commence with the smallest quantity, and increase it until on trial a clear brilliant picture is the result. The bath once in condition, I find it generally continues so for a very long while on being filled up from time to time with a forty-eight grain solution. If from long use a large quantity of ether and alcohol have accumulated in the bath, I pour it into a wide-mouthed bottle or jar and place this in another vessel of hot water, in order to evaporate the excess of spirit. This I have generally done in daylight and have found a blackened precipitate. On filtration I have invariably found the bath work perfectly. Beyond this I rarely like to interfere with a bath once in good condition. And notwithstanding that I find some variations at different times in the condition of the bath, I do not remember in the course of many years of photographic experience to have had spoiled a single ounce of bath by the ordinary process of working.

DEVELOPING SOLUTIONS.

The preparation of these must depend on the class of picture to be produced, as much of the tone of the picture depends upon the developer. The salts of iron are in all cases preferable to pyrogallic acid for positives, giving a better picture with less exposure. Even when the latter is used with the addition of nitric acid the picture lacks brilliancy, and the exposure is long. The class of picture produced by development with the protoxide of iron is materially affected by the nature and quantity of acid with which it is combined. I will mention the results given by two or three different formulæ. The first I shall name contains

Protosulphate of iron	15 grains.
Glacial acetic acid	20 minims.

The amount of acetic acid may vary with the temperature from fifteen minims in winter to half-a-drachm or upwards in summer. Very certain results may generally be obtained with this developer. The pictures are bold and vigorous, possessing at the same time sufficient half-tone to give roundness and good modelling. They are, however, especially with a collodion containing a bromide, generally low in tone, having creamy-looking lights and entire absence of metallic lustre. The addition of ten grains of nitrate of potash to an ounce of the developer gives, from the formation of a small portion of protonitrate of iron, a slight accession of metallic brilliancy and whiteness to the picture.

Another developer giving generally very fine results, contains

Protosulphate of iron	20 grains.
Glacial acetic acid	20 minims.
Nitric acid	2 „

With a collodion iodised with iodide of potassium, about three-and-a-half grains to the ounce, and as much bromide of potassium as it will dissolve — which is a very small quantity — I have produced exceedingly fine results. Some of the best collodion positives I have seen were produced by this combination.

Another developer contains

Protosulphate of iron	10 grains.
Nitric acid	2 minins.

This gives an extremely metallic picture, with plenty of half-tone, not unlike the general effect of a daguerreotype, but greyer in the whites. If the exposure be at all too short the picture is covered with metallic spangles; but if carefully timed the results are pleasing, but not so vigorous as those produced by either of the former developers.

The preparation of protonitrate of iron, or rather of protonitrate and protosulphate combined, given by Mr. Sutton* is an exceedingly fine developer. The formula is as follows:—Dissolve one ounce of powdered nitrate of baryta in sixteen ounces of water, and when dissolved add two drachms of nitric acid s.g. 1.400. To this solution add one-and-a-half ounce of powdered protosulphate of iron. When thus dissolved, filter to remove the insoluble sulphate of baryta. The solution is of an apple-green colour, and contains two

* This differs from the original protonitrate developer of Dr. Dymond in containing excess of protosulphate of iron, and being consequently more active.

parts of protonitrate of iron and one part of protosulphate of iron. A full amount of exposure is required, and the development is rather slow. The resulting picture is somewhat metallic and very pure and brilliant in tone. This developer is somewhat feeble in cold weather, and may with advantage have a still larger proportion of a solution of protosulphate of iron added.

Some of these developers, the first mentioned especially, may with advantage to the tone of the picture be used over again. The principal difficulty this practice introduces is some uncertainty as to the exact strength of the developer after once or twice using, and of the relative increase of exposure rendered necessary.

The addition of sulphuric acid I have not found in any case an advantage. A large amount of unpleasant sparkling effect, with scarcely any distinction between high light and half-tone, being generally the result.

In each of these formulæ a certain quantity of alcohol will be required. The exact amount will depend somewhat on the collodion film, and more upon the condition of the bath. If the bath has been some time in use and contains a large accumulation of alcohol, the developer will require a corresponding amount in order to make it flow freely over the plate without running in greasy lines, each one of which will cause a stain, the result of uneven development. I have found in practice that methylated spirits answer perfectly well for use in the developer.

In all cases I prefer to give just such exposure to the plate as will cause a somewhat slow and deliberate development: a richer, bolder class of picture, with perfect gradation from the highest lights to the deepest shadows being produced. Pictures developed at a blow, or with great rapidity, I have generally found flat and worthless.

It is a point of great importance, and one on which sufficient stress is not generally laid, to wash very thoroughly after development before fixing. Having been a great deal engaged in tuition, I have found this a point much neglected amongst amateurs, and not always well attended to by professional photograpers. It is a most prolific source of stains. The reason probably is that it is very common to develop rapidly, and there is then a temptation to hurry the plate into the fixing bath to prevent over-development, as the development, especially in an over-exposed picture, proceeds rapidly even during the progress of washing.

(To be concluded in our next).

NOTES OF A PHOTOGRAPHIC TOUR IN THE HOLY LAND.

No. XI.

Upon returning from Mount Carmel we found that the *Tarbucket* was to be detained yet another day. Such is the fashion with the Eastern steamers, and we were fain to submit. But as we sat in the cabin in the evening, an idea occurred to me which the rest of the party seized upon with avidity.

It was to go on to Beyrout by land, visiting Tyre and Sidon by the way. Early in the morning I went ashore and found a scribe to write a letter to Hassan, which I sent to Beyrout, with orders for him to return and meet me at Tyre. I wrote in Arabic, not because he could read it, but so that if my messenger overtook him on the road he could get it read to him by a scribe in Sidon or elsewhere. This is the custom here. Then I boarded the ship again, roused our party, and having taken a cup of coffee of François's best sort, we went ashore in a body.

Our intention had somehow leaked out, though I had impressed secresy on my messenger to Beyrout. But he had a dragoman friend, and had whispered to him his chance for a bargain and he had not kept his secret. Accordingly, on our landing, we were beset by a dozen accomplished dragomans — ragged, dirty fellows, who could talk a little Lingua-Franca and ten words of English, every one of whom avowed his perfect ability to show us the wonders of Haifa and St. Jean d'Acre, and of all the world oriental that it should please us to visit.

One of them was a tall Syrian, whose voice was like the small end of a thunder-bolt caught among the bushes — a rugged rumbling voice which was frightfully ludicrous. I engaged him at once on the strength of his voice, and told him what I wanted. He was exactly the man for us. He had a brother at Tyre, who could accommodate us for the night. A capital house he had — it was clean, roomy, airy, and finely situated. He would get us horses — splendid animals — such as the Prophet of the accursed (our man was a Greek Christian) might have been proud to bestride. He would take us to Tyre like princes, and to Beyrout like sultans.

Bekam? insinuated John, in his mildest tone, overwhelmed at the prospect of so much state and splendour, and beginning to think it would cost a trifle to travel in this style.

"How much?"

For the sum of ten pounds Demetri the Syrian agreed to convey us — six to Tyre and four of us to Beyrout — in the style aforesaid, within two days, resting at Tyre for the night in the palace of his brother.

The horses of Haifa are not of the blood of the Prophet's mare. They are not of any blood at all. They are bones absolutely and wholly.

But bones or blood, the Syrian horses can go; and go they did with us across the plain and up the sea-coast towards the ancient city of Acre, which lies at the northern point of the bay, as Haifa lies at the south. The distance is about seven and a-half miles. Demetri led on at a rattling gallop. His voice came back to us once in a while as he chanted a song intended to be gay, but in reality most lugubriously solemn.

We paused at Acre, but I shall not stop to speak of it here. The city is like all oriental cities, and the ancient fortifications — half-repaired, but never able to recover from the terrible shattering they received from British cannon, in 1840 — lie in the sunshine in mournful weakness. We loitered here too long, so that evening came down on us before we reached Cape Blanco.

The road was various. Now we were going at an easy gallop across a plain, and now risking our necks in a narrow mountain pass that no human being ought to dream of riding through in daylight, much less by night, as we were now doing.

We crossed Cape Blanco, a mile or more of mountain climbing and descending, and then a better road brought us to the gate of Tyre.

And this is Tyre! There was a day when the world knew no such grandeur as was here. How are the mighty fallen! "Tyre shall be a place for fishers to spread their nets." "Was not that the prophecy?" said John.

And how fulfilled!

As we rode down the neck of land which connects what was once the island of Tyre with the main land, Demetri, rejoiced beyond measure at escaping from the Bedouins, whom his cowardly heart had been fearing every inch of the way, raised a loud cry, which, in his unearthly voice, sounded like an Indian war-whoop, and dashed down the road. We followed. He whooped and yelled, and shouted, and kicked his beast, and plunged on to the very gate of the city, when a pistol-shot, which John let off for the purpose of startling him, completely and totally dissolved his nervous strength, and the poor Syrian went like a dead man over his horse's head into a mud-hole directly in front of the gate of Tyre. The gates were shut.

When Demetri had picked himself up and ascertained to his satisfaction he was not shot, he began to shout in all sorts of gutturals to the guard within the gate, and at length induced the great door to swing on its hinges. As we entered, the porters, two surly soldiers, reached out their hands for a fee, and I had another chance to practice my stock of Arabic. *Bekam?*

We got off tolerably well for a few piastres, and then went on to the palace of Iskander, the brother of Demetri.

Yea, verily, the palace of Alexander the Great, in the city of Tyre, on the coast of Asia! For Alexander would weigh three hundred at least, and his palace — as for that, perhaps the least we can say is the best.

Nevertheless, let us contrast the ancient with the modern. Here, two thousand years ago, were splendid temples, shrines of magnificent adornment, houses whose ladies were wrapped in Tyrian purples that gave the very name of luxury to the vocabulary of the world. There was no city where men did more joyously exist, where women lived in more luxurious delights, where sweeter incense intoxicated the devotees of Bacchus, Venus, or Mercury. Marble flashed in the sunshine. The carved ornaments of a temple were worth the purchase of a kingdom. It was a trifle to Tyre that it gave Jerusalem the most costly parts of its great temple, and the king laughed at the paltry return of Solomon, who offered him cities and subjects! The whole territory of Tyre, in its greatest days, was never a thousand square miles, perhaps never four hundred; but the still sea, on a sunny afternoon, reflected in its calm surface magnificence and grandeur which had no superior, even to the Pillars of Hercules.

An old man, Ezekiel by name, borne on angel's hands, beheld a vision in the far future, and thus delivered the burden of his foresight: —

"Oh thou that art situate at the entry of the sea, which art a merchant of the people for many isles. Thus saith the Lord God. O

Tyrus, thou hast said, 'I am of perfect beauty.' Thy borders are in the midst of the seas, thy builders have perfected thy beauty. * * * Thy rowers have brought thee into great waters: the east wind hath broken thee in the midst of the seas. All that handle the oar, the mariners, and all the pilots of the sea, shall cause their voice to be heard against thee, and shall cry bitterly. And in their wailing they shall take up a lamentation for thee, and lament over thee, saying, What city is like Tyrus: like the destroyed in the midst of the sea? The merchants among the people shall hiss at thee; thou shalt be a terror, and never shall be any more."

Never was prophecy more literally and exactly fulfilled. Tyre is a terror. In the stormy nights of the Levant, the miserable mariner whose boat, with high lateen sail close-reefed, goes flying down the coast, prays God to keep him off the Isle of Sur, and save him from utter destruction on the ruins of the once mighty city! The water is filled with columns and architraves, and where of old the glory was reflected on the surface, now deep down in the still sea you may sometimes catch sight of the floors on which the princely once trod.

And modern Tyre we were in, and the house of Alexander was the successor of the palace of Hiram.

It was built of stone that may have been part of the palace of that king for aught I know. Possibly these walls had inclosed the ladies' owners of those days. But now a cold wind howled through their crevices, unstopped by the vain plastering of mud. Demetri was right. The house was airy; but it was engaged before our arrival. There were fifty — yes, seventy-five — yes, a hundred thousand fleas to every square yard of the mud floor; and as to the blankets he gave us to lie upon — the blankets were alive — they crawled — they positively moved with the indescribable crowds of inhabitants that filled its texture.

It was a night of horror! Before we slept, or attempted to sleep, we demanded food. Demetri gave us water for our hands before eating, reminding us of the ancient custom of pouring water on the hands, which they follow precisely now, as I have often seen. All the water is carried about these eastern cities in goatskins, which have been taken off nearly whole, sewed up, and in some way cured.

We washed and ate, and then we tried to sleep. D. T.

Meetings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

Despite the cheerless gloom and freezing cold of the evening of December 15th last, our brothers of the south held their usual meeting at the Lecture Hall, Carter Street, Walworth. The President being unavoidably absent, the chair was taken by W. Ackland, Esq., Vice-president.

The reading and confirming of the minutes over, several gentlemen were thanked for donations; among them Mr. Pouncy, who, at the Secretary's request, had generously forwarded three excellent specimens of carbon printing for the Society's folio [a landscape, a portrait, and a copy from some rare old print by Dr. Diamond].

A new stereoscope was exhibited by its inventor and patentee, Mr. Bincks. Its novelty consisted in the power it had of being, by a very simple arrangement, moved outward and forward, so as to suit all visions. Many, Mr. Bincks said, had seen stereoscopically with this who had never done so with any other instrument.

Mr. Alfred H. Wall was then called upon to read a paper announced under the title of *Practical Observation upon Photographs in their Relation to Art.* [See page 3.]

Loud expressions of applause greeted Mr. Wall upon the conclusion of his paper.

The Chairman was very glad to find a subject broached which would, he thought, call the attention of photographers to a matter of great importance. The mechanical had certainly taken undue precedence of the artistic, and we had thus given the opponents of photography a strong weapon against it. The pictorial was the most important and most neglected branch of our art, and he was pleased to find the fact asserted in their Secretary's excellent observations. With regard to white skies, he thought the worst thing about them was that they were by no means necessary, because if the negative had no sky we could obtain one by the printing.

A vote of thanks was awarded to Mr. Wall.

Mr. H. L. Keens rose to support one suggestion started by Mr. Wall, viz., that photography was not necessarily a mechanical art because it claimed many mechanical appliances. Michael Angelo might frequently have been seen from early morn till late in the evening with an apron tied round his waist, and his hands grasping mallet and chisel, cutting from the solid marble block some one of his mighty works, the perspiration streaming from his thoughtful brow the while. The modern sculptor says, "I cannot labour in that manner;" and consequently forms a model in clay, employs a workman to copy it in marble (which by mechanical aid he is able to do very correctly), and then himself adds the finishing touches. Now, if works thus produced are works of art, why may not photography claim the same appellation?

Mr. Hughes: The subject of art photography is one which justly claims serious thought, and Mr. Wall's paper will undoubtedly call the attention of members to a too-much neglected subject; but there are two sides to every question. In the first place, the mechanical and scientific branches of photography are in themselves so absorbing, and present so many and such great difficulties to our operators, that the artistic is necessarily lost sight of; and, in the second, it must be remembered that the art is now in its infancy, and that it has come into our hands not as children, but adults. Photography, like infant art, must first master the mechanical, and then turn to the study of higher effects. The mechanical branches, being acquired with so much ease, would be sure to claim the earliest attention, especially when they were so attractive as in this art; but the higher qualities would be equally sure to assert their supremacy in their own proper order.

Mr. G. W. Simpson: Acknowledging the difficulties of manipulation, he still thought with Mr. Wall that the absence of artistic culture had not its origin in any inability to spare time from the pursuits of photographic chemistry and optics (inasmuch as some of our most artistic photographers were also excellent chemists and opticians), but rather in the fact that photographers had no idea of the effect to be produced. Facility was the bane of the art; so many were content with its worst productions, who could not even conceive a necessity for the mere elementary requirements of art. He did not find either that those who knew little of art were, as a rule, any the better acquainted with science, or *vice versâ*. For his own part, he hoped to see a time when the most talented men of the day would be paid by the parent society to give courses of lectures upon art as connected with photography — such lectures as we found given at all other art societies.

Mr. Hughes: Photography has not yet reached that point, although it is probable that we may yet have a professorship of photography instituted in connection with even the Royal Academy. The Photographic Society is not an educational establishment.

Mr. Wall thought it was, and said: If the culture of art is to be continually deferred until those are prepared to study it who never evince the least inclination to do so, I fear photography will indeed lie long under the stigma of being a mere mechanical art.

Mr. Simpson: Ought not the knowledge of art and its mechanism to be pursued coincidently?

Mr. Keens: As they are by students of painting.

Mr. Howard: Much study had been directed to the least practical theories of photographic science which with greater advantage might have been devoted to the principles of art. It was as if an art-student went to work and compounded colours and made brushes all his life as only preliminary to his study of painting. In more immediate reference to Mr. Wall's remarks upon light and shade in landscapes, he had experienced that more of the picturesque and effective was lost by a fear of getting too much shadow than anything else. Most elementary works recommended the strong illumination of the subject, and introduced a fear of the sun getting into the lens, from which cause students frequently went to work with the light at their backs, and obtained the flat inartistic effects observable in the specimens Mr. Wall had introduced. He always worked, as the members would see by the specimens before them, with a side light.

Mr. Leake thought that, with reference to the artistic in portraiture, it should be remembered that photographers had not that choice of models, and that power of omitting details offensive in themselves, although not of importance to the likeness, which painters had. One lady, with heavenly aspirations apparent in her nose, would insist upon having her head very erect — or upon sitting in an awkward position, simply because Mr. Jones, her spouse, sat so when he was "taken off" — and her friend, Mr. Smith's limbs may be of that peculiarly ungovernable and eccentric description which will defy your most desperate efforts to place them in anything like a tolerably graceful, or rather not conspicuously awkward, position. Again, it is true that a head may be

lighted very artistically, and defects lost in skilfully contrived shadows — but then Mrs. Smith "can't bear them black shadows;" and Mr. Jones sternly inquires if his wife had got a smudgy or dirty face? — or what that black patch means under her chin? — or whether you mean to tell him, sir, that his wife is a nigger?

Mr. QUIN thought such objections more frequently arose from the fact of shadows wanting transparency, and so losing their real character, and held up one of the prints on the table as a specimen of shadow delicately relieved with reflected lights, in the manner pointed out by Mr. Wall.

Mr. WALL: The objections of uneducated sitters are as common to artists as to photographers, and, I think, arise from ignorance only.

Mr. HUGHES said the public were in a great measure the cause of the inartistic character of photographs — for instance, he knew a gentleman who failed to sell a batch of prints to the dealers because they had not the clean white paper skies, so strongly and justly denounced by Mr. Wall. We must not forget that the commercial view of this subject is an important one.

Several other gentlemen entered into the discussion, which grew very animated and interesting, and was occasionally amusingly relieved by the introduction of *apropos* anecdotes. The different agencies now at work for popularising art-education were pointed out, and some opinions expressed relative to the real amount of artistic excellence obtainable in regard to atmospheric effects, while the sensitive medium and optical appliances were in their present condition.

Mr. G. W. SIMPSON thought artists were to blame for neglecting photography, and allowing it to fall into unfit hands.

The VICE-PRESIDENT then announced that Messrs. MARTIN and KEENS would contribute a continuation of the

PHOTOGRAPHIC JOTTINGS,
No. 2.

The first of which was introduced by Mr. J. MARTIN, upon the value of a preparation called the *Crystal Enamel.*

There are few practical photographers who have gone through the process of toning, fixing, and washing a positive print on paper, who can have failed to observe the extreme brilliancy in the high lights and middle tints, and the beautiful transparency in the deeper shadows possessed by the picture while floating in the water employed for the removal of the hyposulphite of soda.

The mere allusion to this will, I am sure, be sufficient to awaken a recollection of the desire which all have entertained that the picture might be made to retain, or have imparted to it, the same amount of brilliancy when dried and mounted; this however it is hardly necessary for me to add has been found hitherto unattainable, if we except the simple coating with gelatine, adopted, I believe, principally by some French photographers.

It affords me much pleasure, therefore, to be able to bring under your notice this evening a preparation which has been in occasional use on the continent for some months, and is being now offered to English photographers by Messrs. Horne and Thornthwaite, of Newgate Street, under the name of *Crystal Enamel.*

I have therefore brought with me, and submit for your inspection six pairs of photographs, one set in the ordinary condition, and the other heated with the enamel; a comparative examination of which will, I am sure, abundantly demonstrate the power which this preparation possesses of imparting that liquid transparency which has so long been a desideratum.

So much for the *apparent* advantages resulting from the employment of this preparation; there is another, however, which is not so obvious at first sight, of even still greater importance.

The permanency of positive prints on paper is the one thing as yet unsecured to photographers, notwithstanding the elaborate researches and numerous experiments so carefully conducted with that object in view; and it is not unknown to those who have given attention to the subject, that this want of permanence is due in no small degree to the alternate and combined action of air and moisture upon the chemical constituents of the picture. Hence it follows that, if these can be protected from such adverse influences, the decomposition or fading will be arrested and permanency arrived at.

I do not mean, of course, roundly to assert that we have in this preparation the grand *panacea* for the great photographic evil; but to say that if it be admitted that a well-washed photographic print is permanent if it were not for its continued exposure to air and moisture—and if it be further admitted that resinous substances, such as are contained in this enamel, have the property of protecting delicate surfaces from the air—then it seems to me that we at least bring together the conditions calculated to ensure the desired permanence; but, whether we shall accomplish that end, of course, the lapse of time only can show.

I should be leaving my notice of this unique preparation incomplete if I did not describe the method of manipulation, which is simple in the extreme.

Having provided yourself with a bottle of the crystal enamel, it is only necessary to prepare one solution, which is done by dissolving (by the aid of heat) 10 grains of Swinborne's gelatine in one ounce of water. This is applied, while still warm, with a flat camel's hair brush over the whole surface of the photograph, including the card-board upon which it is mounted. This coating of size, if I may so term it, is allowed to set hard and dry; the picture is then either hot-pressed or burnished with an agate burnisher; a piece of cotton wool, compressed moderately tight to about the size of a walnut, is next nearly saturated with the crystal enamel, and in this condition is wrapped in a piece of clean calico rag, which is afterwards just lightly touched by the finger dipped in linseed oil: the whole is then gently rubbed, with a rather short circular motion, over the surface to be enamelled, and the application continued until the required brilliancy is obtained; lastly, finish by applying, in the same manner, alcohol and linseed oil.

The usual vote of thanks was awarded to Mr. Martin.

Mr. HOWARD stated that he had prints varnished, or rather polished, in the manner described, which, at the expiration of two years, were in a perfect state of preservation.

Mr. SIMPSON referred to the fact of all varnishes becoming discoloured by time.

Mr. HOWARD found those he alluded to remained perfectly colourless, and that they bore usage remarkably well. They were of French manufacture.

Mr. WALL thought the high polish objectionable, but considered permanence and the increase of detail in, and consequent transparency of, the shadows fully compensated for what, in small pictures, was a very trifling defect.

Mr. H. L. KEENS then contributed a jotting (No. 3) upon

The Proportions found in Figures produced by Art and Photography.

The relative proportions of the human figure are of the highest importance in Art, and in portraiture the peculiar proportions of the individual represented are as necessary to constitute a perfect picture as a correct delineation of the features of the face, and whenever artists have transgressed this principle it has invariably exposed them to the merited censure of the critic.

Gerald Laïsse carefully measured the best proportioned persons, and gives it as a rule that the height of the male figure is seven heads and a half that of the female eight heads. Du Fresnoy says, eight heads are ten faces. Bonomi has published a curious and interesting diagram, used by the celebrated sculptor Gibson, which gives a certain length produced from that of the head occurring three times in the same figure, and another length occurring five times in the same figure, and which correspond to eight heads, as also to ten faces. (Diagrams were submitted.]

It will be perceived that when the figure rests on one foot, according to our general mode (stand at ease as it is termed), the height of the figure is somewhat reduced in consequence of the bending outward of the hip joint and the consequent curvature of the spine. To illustrate this by photography we have but to cast a glance to some fine specimens of whole length portraits which we are able to produce through the kindness of Mr. La Roch, Mr. Barnes, and Mr. Quin; yet it must be remembered that we seldom find persons whose proportions come up to the adopted standard, and in old age the spine becomes more curved and the knees bend forward, shortening the figure considerably.

A good photograph will give a faithful representation of the subject with due proportions. Should an operator therefore be doubtful of the correctness of his apparatus, let him measure out carefully the proportions of a living model, and examine if his photographic image produces the same result.

In the diagram of Bonmi it will be observed that the head is divided into four portions, three equal ones, thus:—first, from the bottom of the chin to the bottom of the nose; secondly, from the bottom of the nose to the indentation a little below the brow, thence to the root of the hair on the forehead; the remaining portion to the top of the head is somewhat less, so that eight heads become precisely equal to ten faces. This is also illustrated by photographic portraits, having a diagram drawn upon them, now before you.

Serious mistakes have been made with regard to the proportions of children; frequently they appear like little men and women. In

infancy the length of the head is one fourth of the entire figure, and as it advances in life the head gradually becomes less in proportion, until at maturity the head is but one-eighth of the whole length. Hence, in consequence, the shoulders of the child appear small. This is illustrated by various engravings after Raphael, Murillo, Correggio, Sir Thomas Lawrence, &c., as well as by photographs of children. [These were produced.]

It has been frequently suggested that the hands are too large in a photographic portrait; this arises from the hands having been generally represented small, but Sir Joshua Reynolds, in his notes on Du Fresnoy, states that the hand is the same length as the face, and the thumb the same length as the nose; these proportions may be seen in engravings after Vandyck and others, and on photographic portraits. [Also produced.] It has also been stated that the mouth is enlarged and the eyes appear too small: with regard to the former much depends on the arrangement of light upon the model. If the shadows are too dark, that which arises from the muscles (the depressors of the angles of the mouth), will appear united to the line of the mouth itself, and produce the effect of a mouth too large. With regard to the eyes, care should be taken that the sitter remain some minutes in the strong light of the operating room before the portrait is taken, particularly when the eyes are delicate, for we naturally close our eyes in a strong light. It is thought that the nose is generally too large, particularly towards the end: this arises also from the illuminating, for if the high light is too broad it will necessarily produce that appearance. The photographs here produced are very perfect, in some the high light on the nose is as delicate as in the fine miniatures by Sir Wm. Ross. With such photographs as these (by Messrs. La Roche, Cotton and Wall, Barnes, and Quin), the public will not find fault, nor think them *too* truthful. The operator will find sufficient to delight him when by his art he approaches the beauties of nature, and will then admire our Sir Joshua, Sir Thomas, Wilkie, and others deceased, and our present Landseer, Frith, and others living, who have not forsaken nature for the phantoms of fancy.

A vote of thanks was awarded to Mr. H. L. Keens.

A number of fine photographs, engravings from celebrated paintings and drawings, were produced in proof of the assertions contained in this paper. Several whole-length photographic portraits were placed beside the measurements given for drawing the figure and found to bear the test, and to have the same relative proportions in every part, in common with good paintings and prints. Among these specimens were a set of very artistically beautiful theatrical portraits, by La Roche, which were very much admired.

Mr. Simpson took up a singularly perfect photograph of a most beautiful young lady, and placing it beside an engraving from the painting of Rembrandt's wife, asked which was the more artistic or beautiful production?—(A general laugh.)

Mr. Quin said the delightful picture in Mr. Simpson's hand, produced by a Dublin photographer, would forcibly illustrate a remark made by Mr. Wall, viz., that but little direct light was needed to produce a properly illumined portrait; for this lady had been taken in a glass room at the bottom of a deep well of enclosing houses.

Some photographs were also produced, taken at Mr. Keens' request by Mr. Quin, from a figure chalked on a wall, being six feet by one foot in height and breadth, and divided into six divisions of one square foot each.

Mr. Quin said, when Mr. Keens proposed the matter he had been inclined to shirk it, fearing to expose a weak point in photography. The diagrams were taken with a whole-plate Ross's portrait lens, three and a quarter inches in diameter, using the full aperture, six inches, and taking the figure six inches in length. He found that no distortion took place; and on taking it again eight inches in length, he was astonished to find that still no distortion was produced. The first diagram was taken from the exact centre of the figure, the camera being perfectly level. The second was pointed at the square below the highest, and inclined (this is the general mode adopted by many photographers when taking standing figures), and the result was, as you see, a general distortion of the whole, none of the squares being equal in length or breadth, and the whole figure being much narrower at the bottom than at the top. Of course, having used the full aperture of the lens, the lines are in parts necessarily out of focus.

Several gentlemen were desirous of making remarks upon Mr. Quin's communication, but, in consequence of the late hour, all discussion upon this and Mr. Keens' paper was postponed until the next meeting, which will take place on the 19th inst.

A paper, by Mr. Leake, jun., on *Failures in the Wet Process: their Cause and Cure*, was announced for the next meeting.

The Vice-President informed the meeting that a sub-committee had been appointed to choose the presentation photograph, which, he hoped, would do justice to the artistic taste and photographic judgment of the gentlemen appointed to select it, and give pleasure and satisfaction to the members. He also announced, by desire of the committee, that all members of provincial photographic societies visiting London would be gladly welcomed to these meetings. He had *personally* received great kindness from many of our provincial brethren at *their* meetings, and, for his own part, should be glad to pay back the obligation in kind. (Applause.) The presentation photograph would, he hoped, be placed on the table at the next meeting, though the copies could not, of course, be ready for circulation for some little time.

Several papers were promised for future meetings, upon the chemistry, optics, mechanics, and pictorial elements of photography.

The Rev. J. Thompson Smith, B.C.L., was duly elected.

The meeting then adjourned.

BLACKHEATH PHOTOGRAPHIC SOCIETY.

A meeting of the above society was held at the Golf Club House on Monday, the 19th ult. The President, J. Glaisher, F.R.S., was in the chair.

The minutes of the last meeting having been read and confirmed,

Mr. Heisch called the attention of members to the great intensity produced by the use of salts of magnesium as iodisers for collodion, and exhibited some negatives, showing the effect of different iodisers on the same collodion. He stated his belief that salts of magnesium would be principally useful in copying prints and such subjects as required decided blacks and whites, but would give too great intensity to produce good effects in an ordinary landscape collodion.

Mr. Melhuish exhibited a stereoscopic camera in brass, electroplated, which combined the qualities of lightness and compactness; the dark slides, seven in number, with focussing glass, packing inside the camera, which was fitted into a leather case.

Mr. R. P. Napper was elected a member of the Society.

After a vote of thanks to the chairman, the meeting adjourned.

LIVERPOOL PHOTOGRAPHIC CLUB.

In consequence of the lamented demise of Mrs. Keith having occurred so recently, it was not possible to continue the ordinary meetings at Mr. Keith's rooms, as heretofore. The usual meeting for the month was accordingly held at Mr. Corey's house, to consider the present prospect of the society, and to debate upon the proceedings for the future.

After considerable deliberation amongst the more influential of the members, it was determined to hold the *seances* of the Club at the respective houses of the members present, in rotation, and to reckon the present as the first of the series.

Mr. Corey took occasion to remark upon the obligation amateurs owed to the writer of the amusing and compendious letters to Eusebius. All of them had been clear, succinct, and eminently practical, but the later letters had done great service to the art. He alluded to the subject of "waxed-paper." Enthusiastic and impatient operators fondly believed there was a royal road to success; and, to save their labour, complicated their solutions with a long list of chemicals. Disappointment made them vary their salts with the like want of success, being all the time unaware that the great requisites were, extreme care in manipulation and less reliance on the susceptibilities of the excited surface, than when collodion was employed. This the writer of the letters had most ably expatiated upon; and so impressed was he (Mr. C.) with the importance of these hitherto disregarded directions — confirmed as he was in this faith by having seen Mr. Keith, when at Furness Abbey, expose fresh plates, with no preservative upon them, for so long as fifteen minutes — that unfavourable as this season must be acknowledged to have been, he selected a piece of paper that had been iodised so long back that the formula for its preparation was a matter of doubt — excited with old aceto-nitrate, black with use and age, taking only the precaution to add fresh glacial acetic acid; and with a prolonged exposure in what was so good a light that he previously would have deemed four minutes sufficient but in this case fifteen minutes, and subsequent patient development with the weak solution of gallic acid, judiciously recommended in the letters — he obtained so good a negative, that it was a matter of regret that the subject had not been more worthy of the pains. He now considered the thanks of the readers were due to the author of the letters to the contumacious and thankless Eusebius, as well as regret at the long journey he appeared to contemplate.

The Messrs. COOK BROTHERS, who are by far the most successful adepts of the Society in this branch, stated that they were fully prepared to bear out the testimony of the writer of the letters, that provided some organic matter, such as sugar of milk, and especially serum, were introduced, the choice of the preparing salt was of little importance.

Mr. COREY objected to the indefinite mode of speaking of serum without giving plain directions for its preparation. Rennet was not always easy to obtain, and was mostly salted, thus containing chloride of sodium, and, as a substitute, acetic acid was too often employed, thus producing decomposition — in the case of iodide of potassium causing a change to acetate of potassa, a non-photographic salt, with a liberation of free iodine, a known retarder of sensibility.

The Messrs. COOK gave in their report of the papers submitted to them at a former meeting. That furnished by Mr. Keith from the mills of Messrs. Pirie presented no albumenised surface though the albumen had been laid twice on each paper, whilst that brought by Mr. Corey from Messrs. Hollingworth's had a very glossy and effective appearance.

Mr. BELL stated he had found a new preservative fluid for collodionised plate in the wine of Champagne. Having occasion to experiment upon this wine in order to see if the saccharine matter it contains could be detected in the microscope to crystallise, he discovered that after four days' exposure to air it was entirely unaltered. The applicability of this to sensitised surfaces of silver salt at once struck him, and he had experimented with signal success. He only waited for finer weather to pursue his research with this stylish medium.*

The next meeting, to take place in a month's time, was arranged to be held at the house of Dr. Cauty.

CHORLTON PHOTOGRAPHIC ASSOCIATION.

THE monthly meeting of the above society was held at the Chorlton Town Hall on the 14th ult. Mr. NICHOLSON, Vice-President, occupied the chair.

After the minutes of the last meeting were read and confirmed,

Mr. GREEN said he should like to ask the meeting if any gentleman had tried the copying by gaslight explained by Mr. Lloyd at the last meeting.

Mr. FAWCETT said he had successfully used Mr. Lloyd's application, and could copy in about seven minutes. He liked the application very much. Whilst speaking of copying and gaslight he should be glad to enquire from the members if any gentleman was employing gaslight for enlarging photographs, as he should be glad to know the best method of enlarging so as to retain the sharp and clear definition of a direct photograph.

Mr. GRIFFITHS said he was satisfied of the correctness of the enlarging process, and had given up working large negatives from nature. He had discarded all his cameras except one, 1-8th size, which took negatives two inches by two and a half. He magnified them at his convenience to the size required by taking a level smooth board three feet long, and fastened at one end a half-size camera with an achromatic plano-convex lens reversed; at the other end he placed a quarter-size camera with the lenses facing each other. The small camera was packed so that the lenses were all centre to centre. A very important matter was to get the diaphragms in the right position: to accomplish this the front lens of the half-size camera was removed and a stop of three-eighths of an inch inserted in the cell to obtain a true centre to the lenses, afterwards the lens was reinserted; a second diaphragm, one inch aperture, was then placed in the ordinary way between the lenses in the quarter-plate camera to cut off spherical aberration, or the edges would be out of focus. To work an enlarged picture he placed a small negative, which he found best from wet collodion, in the plate-holder with the collodion side next the lens in the quarter-plate camera, making it secure so that the shutter could be opened without disturbing it, and also so that no light could pass except what passed through the negative. He had not tried gas for the light, but placed the camera facing the sky so that a clear horizon was before the picture. Should it be placed opposite houses or trees the light would be imperfect in that part, and give a corresponding result, of course. The small camera containing the negative to be enlarged was placed to the light; the exposure was from one and a half to six minutes with his lens, but varied with density of negative and strength of light. He promised to bring some specimens to the next meeting, and regretted that he was not aware that the subject would be brought before them, as it was full of interest to him. He would only further remark, that he could not magnify a collodion-albumenised negative to his mind: the deposit of silver was so great that it magnified with the negative.

After some other remarks from other members,

Mr. HOOPER stated that he should be glad at the next meeting to lay before them a paper process which he thought would be interesting.

After a vote of thanks to the chairman, the meeting adjourned.

PHOTOGRAPHIC SOCIETY OF SCOTLAND.

THE monthly meeting of this Society was held on the evening of Tuesday, the 13th ultimo. Mr. SCOTT ELLIOT occupied the chair.

Dr. Simpson, H.M.I.S., Mr. A. Falkener, Sheriff Hallard, Rev. Dr. Hodson, Mr. D. C. Connell, Mr. R. Pope, and Mr. James Kirk, were elected ordinary members.

The SECRETARY read a communication from Mr. John Sang, Kirkaldy, *On Photographic Printing Frames*, illustrated by specimens of different forms.

A short communication was then read, from Dr. Simpson, on

An Easy Method of Recovering the Silver from Waste Nitrate Baths.

The plan he proposed, and which he had followed for some time, consisted in converting the silver into an oxide, by the process discovered and published by the late Dr. Gregory. This is done by the following means: — Common salt is added to the nitrate of silver solution until it is all precipitated as chloride. The chloride is thoroughly washed by decantation with hot water, and covered, to the depth of half-an-inch, with a solution of caustic potash of the specific gravity of 1·25 to 1·3. Care must be taken to break down all lumps or hard masses with a platinum spatula. The whole must be boiled for ten minutes, or until the chloride has been converted into a heavy jet black powder. If any white specks are observed, the mixture may be rubbed in a mortar, and once more boiled for a short time. When the decomposition appears complete the oxide is to be carefully washed by decantation with hot water until all the saline matter is removed. This oxide dissolves completely and easily in nitric acid, forming a colourless solution of pure nitrate of silver.

Mr. J. T. TAYLOR said he had on several occasions made oxide of silver by Professor Gregory's process as now detailed to them, and could bear testimony to the excellence of the plan, but he thought it involved too many manipulations to find favour with the majority of practical photographers. For some time back he had adopted the much simpler process of precipitating the silver in a *metallic* form, by the addition of a few pieces of copper to the impure nitrate of silver solution. This at once deposited the pure silver in the bottom of the dish, leaving nitrate of copper in solution. After careful washing of the precipitate it might either be at once dissolved in nitric acid, forming pure nitrate of silver, or melted in bars.

On the proposal of Sheriff Cay,

Mr. TAYLOR illustrated his remarks by precipitating the silver from a tumbler of nitrate solution which had been procured. This he did by the addition of two or three penny pieces, which, in a few minutes, effected the desired precipitate. He concluded by remarking that, not only was this method useful in photography, but he found it one of the best and simplest methods for obtaining absolutely pure silver in his own profession.

The attendance was not very numerous, and the business was concluded before nine o'clock.

CALEDONIAN PHOTOGRAPHIC CLUB.

THIS club met in Edinburgh on the evening of Saturday, the 24th ult. Mr. BROWN was called to preside. The minutes of former meeting having been read, the Chairman said:—I see from the programme of to-night's proceedings that our excellent friend Mr. Williams is to address us; but you must pardon me delaying calling on him for a few minutes till I advert to a circumstance which has taken place since our last meeting—I allude to the death of Professor George Wilson, one with whom many of us were intimately acquainted, and all loved dearly. Those of our club who were privileged to associate with him, whether in the capacity of friends or pupils, will not readily forget his profound scientific attainments or endearing kindliness of character. His photographic researches were of an interesting kind, and directed to the higher walks of our art. Fluorescence and its varied phenomena were much studied by him, and it is possible that, had he lived, he would ere long have benefitted the scientific world by his experience of this highly interest-

* Our photographers are becoming perfect epicures; for at a late meeting Mr. Forrest recommended Constantia for the like purpose.

ing and important topic. He was an humble and devoted Christian, and always moved among us as in daily expectation of death. His warning to depart was short. On Friday some of us heard him lecture as usual; on the following Tuesday his noble soul had forsaken his feeble body. His loss is a public one. All Scotland mourns for him. Mr. Williams will now address us, and if I may judge by the various articles before him on the table, I should venture to say he will be very practical indeed in his remarks.

Mr. WILLIAMS: Gentlemen,—My subject to-night, as intimated at our last meeting, is

On Transferring Collodion Positives from Glass to Leather, Cloth, &c.

At our last meeting Mr. M'Naughton hinted his preference for a free and easy style of discussion at our meetings. Presuming that a similar style might be preferred in my treatment of the subject before me, the more especially as this is Christmas eve, when we are all naturally anxious to get back to our friends as soon as possible, I will spare you the infliction of a paper and merely demonstrate the process in question. Here are, you observe, a few sheets of soft leather, coated on one side with a black shining varnish, and here are also a few pieces of cloth, apparently linen, varnished in a similar way. This latter I purchased from a trimming shop in town on my way to this meeting. It is now somewhat extensively manufactured for this purpose. Here again are a few positive collodion pictures; some of them a few years, others not a few hours old. None of them have been varnished. This bottle contains what I call my transfer-varnish, although in reality it is not varnish at all. It is common methylated spirits of wine with a few drops of nitric acid added to each ounce. The quantity in this is in the proportion of seven or eight drops to each ounce of the spirit. Having cut all the cloths to the proper sizes, I now pour over each plate a little of the acidulated spirit, sufficient to moisten it thoroughly, and rear them all on end to drip. I wet the glazed surface of the cloth in a similar manner. Laying the plates down flat—picture up—I now gently, and without disturbing the film, cover each over with the piece of moistened cloth or leather. You will observe I now rub each one firmly from the centre to the edge, in order to press out air-bubbles, and conclude this part of it by placing them all between the leaves of this old scrap-book, and covering all with this weight to keep them in close contact. These should remain together as long as possible: not under ten minutes. For a valuable picture, I would consider half an hour quite short enough. When putting them aside, I see I have forgotten one, and, while the others are drying, I will make this one the subject of an experiment. I cover the back of the cloth with another piece of glass the same size as the glass picture, and clamp them together with these American clips. This will ensure contact. I now heat it before the fire, and, after a minute, remove the back glass. A further exposure to the fire renders it quite dry enough to attempt the removal of the picture. This I do by starting the collodion at the upper end, and, laying hold of the cloth by the corner, I lift it gently. There! You see the transfer is effected at once, and very successfully too, although done in much too hurried a manner. You will observe, too, that the picture is much more brilliant now than when it adhered to the glass. The glass itself is now ready for another picture. In the time you are examining this portfolio of transferred pictures, all done (with the exception of the hurried drying) in exactly the same manner as this, I will examine the others and see if they are getting ready. [The contents of Mr. Williams's portfolio were here handed round among the members, and were very much admired. The pictures included all kinds—plain and stereoscopic, portraits and views. In answer to a question Mr. Williams said he got as much cloth for fourpence as answered for four or five stereoscopic pictures.] He then resumed:—I find the pictures dry enough, and will now attempt their removal. I do this in exactly a similar way as I did the other. If a *stick* occurs in raising the film, I drop a little distilled water, which permeates between the glass-plate and the collodion film, assisting the raising of the film. Thus have I successfully transferred these ten pictures; and in sitting down, I thank you all for your patient hearing, and if in any way I can throw more light on the subject, I will esteem it a favour if any gentleman will ask any questions relative to this subject.

Mr. M'ADAM said: This is a subject which admits of no discussion whatever; its many advantages cannot possibly be doubted. I should like to inquire, however, who is the discoverer of this useful little piece of manipulation?

Mr. M'NAB: In absence of data to determine this question, I can only say that there will be no difficulty in getting at least half a score claimants for the honour of the discovery of this simple little piece of manipulation; as every one acquainted with the history of photography knows that no sooner has there been any discovery made, than some hungry cormorant, a claimant for fame and immortality, is always ready to pounce upon and seize the prize from its lawful owner.

Mr. BROWN: That beautiful uranium print of the lady of our esteemed host, which I see hanging over the mantlepiece, suggests a number of instances corroborative of Mr. M'Nab's statement. Although it is notorious to all who have been at the trouble to enquire, that Mr. Burnett, of this city (whom I hope to introduce as a visitor at our next meeting), is the real and sole discoverer of the uranium process, yet will it be believed that, at so recent a period as the late meeting of the British Association in Aberdeen, a French Abbé had the effrontery to stigmatise Mr. Burnett as a pirate and Nièpce de St. Victor as the discoverer of this process! This arrogance, ignorance, or something worse, was intensified (to use a photographic phrase) by the fact of the learned (?) body allowing the imputation to pass unquestioned or unnoticed.

CHAIRMAN: Before separating, I would call the members' attention to the splendid exhibition, now open, under the auspicies of the Photographic Society of Scotland. For neat manipulation, artistic selection of subject—in fact, for general excellence—the works displayed far surpass anything I have yet seen either here or in London.

Mr. MONTAIGNE: This is a subject, Mr. Chairman, which admits of two opinions. I at once admit that there are pictures in this exhibition equal to anything hitherto produced. The *general* excellence of the exhibition I do not so much question; but many exhibitors, as well as the public, will at once see that merit or excellence does not always occupy the "line." There is, for instance, a constructed group (representing a well-known clergyman and his *session*) of very great merit, which has its location in such a position as to necessitate absolute kneeling in order to see it; while on the other hand, situated in the *very best* position in the room, is a portrait of very large size, purporting to be a pure photograph by an American artist. Now, any one without glasses would see at once that pigments and camel's hair, rather than chemistry, have been employed in its production. The members of that society should really present their hanging committee with magnifying glasses.

Mr. BROWN admitted that he had heard many complaints, both loud and deep, relative to alleged undue favour in the hanging of some of the works. However, that might be want of *discrimination*. This appeared to him the only alternative to escape from such a charge.

The meeting separated at nine o'clock.

Exhibition.

EXHIBITION OF THE PHOTOGRAPHIC SOCIETY OF SCOTLAND.

I HAVE again made it convenient to "conjoin business with pleasure," and send you some notes regarding the progress of our northern friends in the beautiful and useful Art of Photography.

The Exhibition was opened on the 16th ult., as I am informed by the *Mercury* of the 17th, which gives a brief account of the private view of the evening previous, and, after giving the names of the grandees who were present, winds up the peroration by stating that "Carlow, Cobalt, and Madder" had *sent* (!) some fine specimens from Kensington Museum. Being tolerably familiar with the names of the great majority of photographic artists, on entering the exhibition room, which is the same as last year (90, George Street), I wended my way on a voyage of discovery to find out the productions of these gentlemen, when, lo and behold! matters turned out as I had anticipated; these were the *modes of production* and not the names of artists at all.

There were four proofs—two in carbon, a portrait and landscape, the finest that I have yet seen produced by this process: in both the detail and half-tone are excellent, but the whites and sky are a dull cold grey, yet very superior to the copy exhibited by Mr. Pouncy the previous year. The cobalt one is a small portrait, two inches by one, with a warm tint of variegated blue, and the madder (crimson red), a portrait of a lady, about an inch square, giving a curious but pleasing effect. With regard to their permanency I can say nothing; but your able chemical correspondent, Mr. C. J. Burnett, will probably be able to inform you on that matter.

The most peculiar and prominent picture in the Exhibition is a panoramic view of Lucknow, in six divisions. The respective sections are not harmoniously toned, but it is bold, clear, and well-defined, giving a very accurate realisation of that great and wonderful city. There are in all nine hundred and twenty separate

views, counting the stereoscopic frames as one only. Five hundred and sixty-five of these are of Scottish origin; the remaining three hundred and fifty-five are from either foreign artists or sent from foreign climes—a large number being from India. Several artists have deluged the rooms with a plethora of specimens. The Messrs. Hay, for instance, send forty-five; Messrs. Cramb, of Dundee, thirty-five; Mr. M'Craw, thirty-five; Miss Taylor, twenty-nine; Mr. Wilson, of Aberdeen, thirty-one; Mr. Scott Eliot (amateur), thirty-one; Mr. M'Leay, twenty-six; Mr. Horatio Ross (amateur), twenty-four; Messrs. Maull and Polyblank, twenty-five, &c. I understood that, in consequence of the same thing occurring the previous year, a bye-law had been recommended or introduced by some member of the Society, to the effect that none were to exceed twenty specimens in one year, which is certainly an abundant limit, and only fair-play, to allow all to have their pictures exhibited. An intelligent dealer informed me that the Society had more pictures sent them than they could conveniently exhibit. The hanging committee, however, dont seem to discard proofs because they are of humble pretensions, of which No. 209 is an example. The catalogue states it to be the portrait of a gentleman, but who looks very like a condemned felon, seated solitarily in his cell, leaning his back against a perpendicular panel of timber, with one leg over the other, looking very sorry for himself — the foreground being very like a portion of a river or sea-beach, terribly out of focus. There are a few more pictures of the same character. I am persuaded had these been the product of some poor professional, instead of an office-bearer, they would certainly have been turned to the door and quietly disposed of.

Another amateur office-bearer has gone all the way to Venice to invest his nitrate of silver in a few blurred, ill-focussed pictures of that palatial city, and, while packing up his other photographic traps, had evidently forgotten his spirit-level. Architecture seems to have been in a merry mood when this gentleman planted his camera amidst that city of the sea, and disposed to dance a jig; for the perpendiculars of the buildings are nowhere. I allude especially to No. 126. *A Canal in Venice*—a picture awfully blurred and worthless—(No. 128), is equally poor, the camera having been tilted to embrace the field, clearly indicating, by the curved marginal lines, that it was not taken by one of the new lenses so bepraised by the committee of the Photographic Society of Scotland. Nevertheless this illustrates the charm and fascinating power this science has over its devotees, when gentlemen are impelled by it to make long, troublesome, and expensive journeys, to procure for themselves what they could purchase at home for a few shillings, infinitely superior proofs, and taken by *artists* on the spot. I hope this indefatigable photo' will be more successful on some future occasion.

I must try to mix a little sweet with the bitter, and give you an account of some things that are better; but knowing, as I do, your reverence for truth, and the rigid, inflexible way in which you fearlessly state your opinions in your criticisms upon the photographic art, I deemed it best to endeavour to give an accurate view of the *tout ensemble*.

In this year's Exhibition there are some very large portraits — that is, *enlarged* and coloured, as well as plain; but in these I find no appearance of progress. No. 269 is one by Mr. Brady, an artist of New York, in which the face is entirely stippled over, and which would require a couple of days hard artistic labour with the pencil. This picture is hung as an untouched photograph, which it is *not;* and, if I remember right, by one of the regulations of the Exhibition, promulgated by advertisement in the now British Journal of Photography was, that all such productions were to be labelled as *touched* or *painted pictures*.

Such being the case, this picture, according to the Council's own rules, ought to have been rejected and allowed no place on their walls.

Messrs. Lyndon Smith and Raven, who took the medals last year, are large contributors; and Mr. Smith has not only doubled his diligence, but also the number and size of his pictures and lens. He sends nine large landscapes, mostly from the sombre, gloomy, misty region, entitled the "Valley of Desolation."—Mr. Raven contributes twenty-two subjects, but I do not think any of these show any marks of progress; but no wonder, for, as he is doubtless carried by the same zeal and devotion to the discharge of his parochial and clerical duties, little time will be left to prosecute the science of photography. — Mr. Wilson, of Aberdeen, sends some thirty exquisite landscapes, and one frame of stereoscopic views which surpass in beauty and definition all the photographs that have been publicly exhibited in Britain hitherto; but, as you have noticed these so recently yourself, I shall pass them over. — Mr. Rodger, of St. Andrew's, contributes twenty-four, principally portraits, of rare excellence and beauty. One of these is an artistic family group, consisting of twelve, all beautifully delicate, and in good focus, with one tiny exception — a little boy in the foreground has moved, and has three eyes and partially two heads — otherwise it is a perfect gem, and I am much mistaken if the Society's medal will this year be awarded to misty, woolly, waxed-paper pictures.

I have not time for further remarks at present, but will probably communicate with you again in a few days, more in detail.

SEL D'OR.

Practical Instructions on Coloring Photographs.

By Alfred H. Wall.

CHAPTER VI. *(Continued).*

THE MOUTH

Next claims our attention. Before touching this most important feature, carefully study its formation and the various half and intermediate tints, which, betraying *the exact degree* of muscular action, rule the expression. Then, with the same tender care as before, begin with the upper lip, preserving its exact tone and shape, but strengthening the delicate reflected lights which play in soft minute touches about the centre of the shadowed half of the upper lip, near the corners, and parallel with the line dividing it from the lower lips, and give delicacy, roundness, transparency, and truth of texture. The lightest portion of the lips, when compressed, will be found near the centre, because the muscles then draw them inward from the light as they approach the corners. The amount of projection in the lips will be indicated by a soft shadow* cast by the upper one upon the lower, and by a strong or faint light upon the latter; it is therefore important to preserve the exact relative depth of the shadows here, as a want of this care endangers the likeness. The upper lip is always, more or less, in shadow. A delicate reflected light will be found tracing the outline of the lip, faintly or strongly, according to its peculiar form. Remember the remarks made upon the treatment of polished bodies in photographs, and lower the large light upon the lower lips to receive a smaller high† light of exactly the same shape, which may either be left out or touched in with a little Chinese white.‡ Of course this light will, by its form and brilliancy, indicate the lips' true contour and prominence. The hollow (which indicates a smile), at the corners of the mouth will give a shadow on the light, and receive a faint soft light on the shadowed side. The strength of the shadow cast by the lower lip indicates its fulness, and, less distinctly, its shape. The darkest portion of the lips melt imperceptibly into the general shadow on that side.

HAIR, EYE-BROWS, AND BEARD.

In beginning any part of your picture always consider its nature and effects. Hair is the most glossy when smooth, and very much less so when rough; the high lights will (by their degree of brilliancy), therefore go far to indicate this point. Don't let it appear as if newly greased and combed. Preserve the character of the photograph in the larger divisions of the hair, and its high lights, shadows, and reflected lights, but never attempt to individualise particular hairs by putting in a series of fine lines, as many painters do. All effect, and all the charms of this really beautiful subject, will otherwise be destroyed. (My aim is not elegant composition but effective teaching, therefore I again repeat my frequent caution, viz., do not let your lines be hard, and do not attempt to put any of them in with one stroke of the brush, or at any rate, *not yet.*) Remember that hair partakes of the nature of polished bodies. Soften the outline of the hair into the background, but do not give it a softness foreign to nature (nor make it woolly) in the attempt. A flowing grace should characterise its masses, and a vigorous marking of its high lights and deep shadows give additional softness (by contrast) to the rounded semi-transparent contours of the features. But again, with vigour it must not acquire a character of solidity, as if nothing less than a tempest blast could raise it, but while as hair it must be light as a polished surface, it must have strong shining lights and intense darks, and as

* The shadow cast by projecting bodies.

† Highest or brightest lights — those nearest the illuminating source.

‡ Be sure that this pigment is pure as otherwise it will darken, or blacken, and destroy your picture. Many Chinese whites (so-called) prove to be no better or more permanent than the common flake. If I was addressing a pupil in person, I should not hesitate to inform him where I procured the best water colours, and in despite of fearful delicacy, I will here state that my first and only master, the late highly respected and deeply regretted, Mr. Charles Foster (one of the best of a now decaying school of miniature painters, and a clever artist to boot), recommended me to purchase Newman's colours, which I have ever since used, and have never found surpassed. The fact is of sufficient importance to the amateur to justify this notice, although I may risk unpleasant comment by so doing.

a transparent mass it must possess extreme softness. Every lock should be traceable to its root. I have given you a difficult task, and one which very few master, for hair is indeed one of the most difficult things to paint well.

The Beard or Moustache.—The latter will be lightest, being the most prominent; preserve the transparent character it has where thin, and remember that it can never (naturally), be quite as dark as the hair, for not being so thick, it is consequently modified by the skin being seen through.

The Eye-brows must be put in with a touch suggestive of its smooth and silky, or rough and irregular character, &c. Its darkest portion will be found nearest the nose. Do not destroy the faint or strong shadow observable beneath it, neither in shape or tone.

The author of the preceding paper has, in order, to render his communications of greater practical value, kindly undertaken to criticise the work of, and give advice to, students, in colouring, through the medium of these pages, for which purpose specimens may be sent, with a stamped and directed envelope *for their return, to* A. H. Wall, Esq. 11, The Terrace, Walworth.

G. A. Hill.—See maxims 2, 4, and 5. Print on salted paper, roughen with very fine pumice stone, and proceed as usual, using the soft Swiss crayons. I shall include a short lesson on this subject. See a small work by H. Murray, published by Windsor and Newton.

J. D.—It is not often prepared by colour makers: I procure it from Newman's. See note to the present portion.

A Lady Amateur.—I perceive you are in earnest, and reveal great promise. Place the next between two pieces of millboard; this was damaged (as you have seen) in coming through the post. "So far so good."

One of my Old Pupils.—You have given me something to be proud of. I put your note in lavender.

Cornish.—Did we not draw together at the School of Design? If so, come and see me, or send your address. With regard to the positive—the likeness is evidently destroyed. Use more care and less colour; the carnations are too raw, and the blues too pure. Give up dry colours, and take to oil or water.

G. B.—The new French vehicle was recommended for another purpose to Mr. Daintree; but by substituting white for yellow wax and using more turpentine, it may answer yours. It dries very hard indeed, and, it is said, rapidly; but I have not tried it. When dry, it will bear any amount of friction. The water-glass is better in theory than practice, being destructive of very many important colours.

J. P.—Not for an instant. The fault is in the picture, which is so faint that you could not avoid effacing it with colour. Choose a vigorous, well-marked positive, especially when you finish highly. Varnish is a great advantage to powder colours, giving them transparency, mellowness, and permanence. It is a mistake to leave them unprotected. With regard to your concluding remarks, I hope to say something on the subject in another form some day.

Foreign Correspondence.

Paris, December 26, 1859.

Messrs. Maskelyne, Hardwich, Hadow, and Llewellyn's theory of the nature of the photographic image produced by the salts of silver does not meet with a ready acceptation by our French *savans.* The report presented to the Meeting of the British Association at Aberdeen does not appear remarkable for clearness. The point at issue between these gentlemen and Messrs. Davanne and Girard, the French chemists, who have most elaborately studied the question, appears to be this—whether the silver, after light has acted upon it, is in the state of sub-chloride, or in the metallic state. The French chemists incline to the latter view; the English to the former. Messrs. Davanne and Girard having published the details of the experiments whereby they arrived at their conclusions, we are better enabled to appreciate their value than we can do with the English report, which gives only the conclusions at which the experimentalists arrived. For my own part, I cannot but think that the photographic image is composed of metallic silver, the particles being enveloped in organic matter; and shall maintain that view until another is conclusively established. It is very desirable, for the credit of the art, that this question should be satisfactorily settled.

One of our most distinguished photographers, Ernest Mayer, has originated a benefit society, under the title of "Photographic Union," a description of which, I think, will interest you. Most professions and crafts have established similar societies among their followers, and of their utility there can be no sort of doubt. The disciples of photography and its auxiliary arts have become so numerous that a benefit society is as much needed among them as among any other artists or artisans.

This Photographic Union consists of photographers proper, colourists, retouchers, and others devoted to the art: there are enrolled members, honorary members, and donors, also members. The objects of the society are to procure medicine and medical aid for its members; to provide the funerals of those who die poor, and to assist the widows, and the orphan children of deceased members who have not arrived at fifteen years of age; and also to bestow pensions on those who may become unable to pursue their calling from infirmity, accident, &c.

The number of members is at present limited to five hundred, which number may be hereafter increased. The number of donors and honorary members is unlimited. Members must be over eighteen and under fifty; subscriptions paid monthly. Members become entitled to the advantages of the association at the expiration of three months after they have joined it.

Members are entitled to medical attendance and medicines during the whole period of their illness, and to a payment of one and a half franc a day during the first three months; the Council to determine if the allowance should be continued after that date; and if it be, only half that sum to be allowed. If the illness continue longer than six months, the member to be considered as incurable, and assistance will be rendered on conditions arranged by the Council.

Members who have been enrolled twenty years, and have attained the age of sixty years, will be entitled to pensions.

I am not aware that a similar society exists among English photographers; I have, therefore, communicated the particulars to you, in the hope that the suggestion of this union may lead to the formation of a similar society in England. I think it well worthy serious consideration.

Mr. Maxwell Lyte has received a silver medal from the Bourdeaux Photographic Society, as an acknowledgment of the excellence of the proofs he sent to it for exhibition.

Mr. Woodward's solar camera has roused the Parisian opticians. M. Chevalier refers to his megascopic camera, invented many years ago; and M. Jamin to one of his invention, made some five years since. This consists, first, of a bi-convex or plano-convex lens, arranged so as to throw a luminous ray through the photograph; and second, of a mirror mechanically inclined, so as always to throw the ray upon the centre of the lens; and third, of a combination of achromatic lenses intended to recover the image of the negative, and project it upon a screen, which is movable according to the size it is desired the image should be.

He has not adopted a special arrangement of lenses to produce the image. All achromatic combinations are suitable whenever the focal distance is double the size of the photograph to be reproduced. Besides, the shorter the focal distance, the larger the image is at a short distance and the stronger the light, and consequently the more rapid the reproduction.

For this instrument to act satisfactorily it would be necessary to connect it with clock-work, so that it could be made to follow the course of the sun, and the light reflected from the mirror be cast on the centre of the lens. In the experiments already made each proof required about an hour's exposure to the action of a powerful sun light. J. P.

New Books.

Harmonious Colouring as applied to Photographs. By an Artist-Photographer. Second edition.

London: W. Kent & Co., Paternoster Row; James Newman, Soho Square.

We had occasion to notice this work favourably on its first apearance not many months back A second edition having been called for within so short a space of time is no slight evidence of its popularity, and we may reasonably suppose also of its excellence. The first thing which we notice as new is a copious index prefixed to the book, which will no doubt be duly appreciated, for nothing can well be more tiresome when wishing to refer to some particular point that may have struck the reader when first perusing it, than the annoyance of not being able to hit upon it again without going through it *de novo.* The coloured illustration of the effects resulting from the admixture of the primaries and secondaries with one another has been omitted; but the price has been reduced more than fifty per cent. as a compensation.

The whole work has undergone general revision, and a considerable addition has been made to the chapter on colouring *alabastrine* positives, as they have been called—that is, positives whitened by the use of a solution of perchloride of mercury. There is one addition which will no doubt prove a very great attraction to amateurs especially—a chapter on colouring stereographs, the more especially as the method of operating appears to us to be easiest of the whole; but we are perfectly unsophisticated in the practice of this art, so we may be mistaken.

Correspondence.

THE ARCHER FUND.

To the Editor.

Sir,—I have read with much pleasure in your widely-circulated Journal the letter of a "London Photographer" on the subject of the Archer Fund, and the humane wish with which, in a foot note, you so considerably commended it to the notice of your numerous and charitable readers.

Although not profiting materially from the practice of photography myself, I have yet felt called upon, in however slight a degree, to acknowledge my obligation to the late Mr. Scott Archer — an acknowledgment which I have made by forwarding to the Archer Fund Committee* the small *annual* donation of one guinea. I am of opinion with those who think that the photographic world have unquestionably in this case a moral duty to perform, the which, if it be withheld, will infallibly reflect discredit upon the profession; and it is with professions as with individuals — the performance of a moral duty can never be deferred, much less omitted, without moral injury, while the converse holds equally good; and the performance of every such duty is attended with increased dignity and self respect, and all their concomitant advantages — a moral reward, which is always proportioned to the cordiality and promptitude with which the duty is performed.

It cannot be that any one, much less a parent, can day after day practise the collodion process without now and then turning a thought to the orphan children of the man to whom above all others he is indebted for, as the case may be, either his pleasure or his profit.

A noble example has been set in this instance by Her Majesty the Queen and His Royal Highness the Prince Consort, who, with a readiness which must have given double value to their generosity, acknowledged most unequivocally their sense of the obligation that was due, not only from photographers and all who benefit, either directly or indirectly, from photography, but also from the public in general, for whom this beautiful and useful art has presented a new and extended pleasure, of the most refined and elevated description.

Sorry should I be, Sir, for the credit of all that is noble in human nature, and most of all in Englishmen, to see either the one or the other indifferent to the claim of these poor children, or that strong claim either niggardly or sluggishly acknowledged. Depend upon it that it would be a reproach that would adhere to them indefinitely.

I am yours, &c.,

Braemar, Aberdeenshire. THOMAS PEARCE.

* Sir W. J. Newton and Roger Fenton, Esq. — Ed.

DRY PROCESSES.

To the Editor.

Sir, — What is the *rationale* of the dry process? the albumen is always washed off. What effect has albumen, or any other similar fluid, oxymel gelatine, &c., on the *sensitised* plate, which thus preserves its sensitive qualities for such long periods? Under what circumstances was the discovery made, and what *led* to the adoption of albumen, &c.?

I am yours, &c., A SUBSCRIBER.

[Albumen, &c., combines with the nitrate or with the oxide of silver, forming thereby a compound capable of becoming blackened under the influence of light. Iodide of silver *readily* receives the actinic impression, but is not thereby blackened; it however communicates the necessary impetus to the organic or other compound of silver in contact with it. The *whole* of the albumen, &c., is not washed off, because it is in part rendered insoluble in water. Collodion simply sensitised, washed, and dried, is well known to be sensitive to the actinic rays, but the difficulty of its employment alone consists in its impermeability to the developing solution when dry, and its tendency to be stripped from the plate during the operations of developing and fixing. The albumen materially assists not only in rendering it more easily acted upon, but also in causing its adherence to the plate. It is commonly asserted that pure iodide of silver is insensitive to the action of light: we have considerable doubts on this point; it may be only a question of development; indeed certain experiments which we have performed tend strongly towards this conclusion. The knowledge of all these facts was not arrived at by a single experiment, of course, but it appears to have arisen somewhat as follows:—It was at first thought that in order to retain the excited collodion film in a sensitive condition, *moisture* was a *sine qua non*—hence the nitrate of zinc and nitrate of magnesia processes suggested by Messrs. Spiller and Crookes: these salts being highly deliquescent were intended to counterbalance the effects of evaporation, by their power of absorbing moisture from the atmosphere. Honey, syrup, and oxymel (a preparation of honey and vinegar), glycerine, and the like were shortly substituted as more conveniently applicable, the principle however being supposed to be nearly identical with the preceding—that is to say, they were applied with a view of preventing the moist film from becoming dry, and successfully so; but in practice it was found that they did more than this, the negatives obtained acquired much greater intensity than without the use of the honey. Dr. Mansell, of Guernsey, pointed out that a compound insoluble in cold water was formed between the honey and silver salt. About this time a *dry* collodion process was being sought for in every direction. Mr. Mayall stumbled upon the fact that if a collodionised plate were sensitised in a nitrate of silver bath which had been used for *albumenised* plates, after washing and drying the former, they were impressionable by light, and subsequently developable. Mr. Barnes also succeeded in employing plates coated with collodion upon albumen, sensitised, washed, and dried; but the impression at that time was strongly maintained that success was principally dependent upon the structural condition of the collodion. In France, M. Taupenot thought of coating a collodion film with one of albumen, having the idea that as a sensitised film of dry albumen would keep active for a considerable time, though slow to receive the impression, and as collodion readily received the actinic impetus; by using both he hoped to gain the advantages due to both films. In this he was to a considerable extent successful, and it is indisputable that the molecular condition of the surface exerts a considerable influence upon the result. The Taupenot process was certainly the origin of the various modifications of the collodio-albumen processes. Dr. Hill Norris, of Birmingham, was of opinion that the only reason why collodion when moist is more sensitive than when dry is, that in the latter condition it is less permeable, hence he suggested the employment of a film of gelatine, applied while the collodion is still moist, with a view to preventing the absolute coherence of the particles of the film. The Fothergill process arose out of the collodio-albumen ones in consequence of a better knowledge of the part played by the albumen to which photographers had by observation attained; but it is principally since the practice of the Fothergill method has been pretty commonly adopted that the true part enacted by the albumen has been ascertained. Such are, we believe, the leading features of the various steps that have resulted in the dry processes as at present practised.—Ed.]

DIRECT TRANSMITTED POSITIVES.

To the Editor.

Sir, — Your notice of M. Poitevin's endeavours to produce direct transmitted positives in the camera reminds me of a phenomenon which has often come under my observation, but which I have never been able to account for, and seldom have been able, with certainty, to reproduce. After exposing a collodionised glass-plate, and commencing to develope in the usual way for a negative, I have found that upon admitting white light for a second before the development is complete, the result is not a negative picture, but a positive by transmitted light: the lights are transparent, and the shadows dark. I have not had time to follow up the process, but I doubt not that by careful experiment and observation of the proper time for letting on the light, for shutting it off again, and for discontinuing the developing, the result will be as constantly perfect as I have often by guess alone obtained it. I am, yours, &c., H. E. N.

[The method above suggested for producing direct transmitted positives was brought forward at the October meeting of the French Photographic Society, as well as the more certain one that we gave. Mr. Rippingham, of the London Society, also made use of it some time back. It is, however, exceedingly uncertain in its results, *especially as regards the half-tones*, and it not unfrequently occurs that a part of the plate is developed as a negative while the remainder comes out as a transmitted positive. We have much greater hopes of M. Poitevin's mode of manipulation; but in any case would be glad to find some of our practical photographers at work upon the subject in either direction. — Ed.]

Photographic Enamel. — We have on many occasions had enquiries from various correspondents for information relative to the brilliant surface noticeable upon some stereoscopic slides. No doubt many of these owe their lustre to the use of very highly albumenised paper, but some have a polish still greater than can be thus accounted for. We have recently received a small specimen photograph from Mr. S. Gans, 17, Queen Street, Cheapside, London, with a surface as polished as some of the elegant French cardboard boxes, so attractive at the present season; and this, we are informed, is due to the use of what he calls *photographic enamel*, but of what it consists, and how applied, we do not know. We notice it, however, as probably supplying the requirements of our enquirers. We should not think it possible to produce a more lustrous surface than we find upon the specimen before us. Mr. Gans asserts that the enamel tends to the preservation of the photographs: of this we could judge better if we knew the composition of it, but it is not improbable that it may protect the proof from atmospheric deleterious influences.

ANSWERS TO CORRESPONDENTS.

☞ A Photographic Sheet Almanack is given free with the present No.—The Title and Index for the Volume for 1859 will be issued with our next.

D. T.—By all means take No. 2.

J. Teesdale.—You will find a reply in our present Leader.

C P.—Iodide of ammonium, two grains; iodide of cadmium, two grains; bromide of cadmium, one grain.

Enquirer.—We report strictly as we find to be the case without flinching; so if you seek it you must take your chance.

Brookfield.—See our notice of Mr. Wilson's Scottish gems, in the present number. Mr. Sedgfield also has produced some fine interiors.

Martha N——.—Photographic printing is a very good occupation for a female; in fact, females generally turn out the best printers.

Wm. Birkenshaw.—If you do not find a satisfactory reply to your enquiry in the pages of the present number, you will certainly do so in our next. We expect, "before going to press," an article on the subject.

Stupid Tom.—Not so stupid. We are not surprised at your perplexity: every one advertises the *best* in the market; and as it is impossible that more than one can be truly so described, the absurdity of such a statement is patent enough. However, to assist you we will suggest that you should procure some of Nos. 4, 7, and 8, on your list, which are all very good, but differ somewhat in working. Try which of these suits you best and stick to that one.

J. Andrews.—See reply to "Inquirer."

North London Photographic Association. — Owing to a press of matter, and the late hour at which the copy reached us, our report of Wednesday's meeting is left over.

*** Several matters for criticism which we have received are necessarily postponed. We have been obliged to give extra space in this number, and yet want room; besides which we have not yet had sufficient time to study properly the subjects omitted, in order to give a report according to their merits.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 110, Vol. VII.—JANUARY 15, 1860.

Whatever may have been the case with the first two meetings of the Photographic Society for the present session, that held on Tuesday, the 3rd instant, was a decided success. The paper read was by Mr. Hardwich, and it appeared to give general, not to say universal satisfaction; which is not surprising, seeing that, as usual with this gentleman's productions, the matter was both interesting and instructive, dealing more with principles than with practice, though the latter element was by no means overlooked. The discussion was both animated and much more to the purpose than is sometimes the case, less digression than usual having been indulged in; yet, for all that, the sitting did not terminate until some time past ten o'clock. There were various matters exhibited—amongst them Mr. Smartt's portable dark tent, with some recent improvements, which Mr. Heath described; a number of negatives by Mr. Barnes, taken upon dry collodion, with some sort of written description, which nobody had time or opportunity to read, appended to one or two of them; and some indifferent positive proofs labelled *calotypes*, which were not described. There were also on the table some of Mr. Russell Sedgfield's beautiful stereographs, which needed no description; and some carbon prints by M. Joubert, which the producer declined to describe—altogether producing an effect "more easily imagined than described."

We have at length experienced some curiosity to know by what method of procedure a carbon print can be produced, that is, such carbon prints as were exhibited by M. Joubert, which we are ready to admit were *very good*, more nearly approaching to silver prints than any that we have hitherto seen. The lights were clear, the half tones delicate, and the shadows intense—not quite so transparent as might be desired, but still good. There was one peculiarity that we should like to have accounted for, viz., the sides of the picture were transposed, some letters visible on a bill requiring to be read from right to left. We understood M. Joubert to have asserted that the proofs were absolutely light-printed by direct contact with the negative, or we might have inferred that they were obtained by an impression having been first transferred to metal or stone, from which copies were procured by some kind of chemical printing—a highly useful application no doubt, but still not a solution of the problem of carbon photographic printing, as generally understood. It is possible that, in using the term "negative," M. Joubert meant thereby simply the glass original which he employed in succession for each of his proofs, but that it was in reality a *transmitted positive*—in this case the problem may really have been solved, and we may be much nearer to a revolution as regards silver printing than most of us are inclined to expect. Two very important steps in advance have been attained—the rendering of half-tone and cleanliness of the lights, these having been the two greatest stumbling-blocks hitherto existent in this branch of photography.

While on this subject, we may venture to make a few comments upon some specimens not very long ago issued by a contemporary, and purporting to be *photographic* carbon prints by Mr. Pouncy, from a negative by Dr. Diamond. It is not a little singular that these have also their *sides reversed* with regard to the original, and that the *negative* is simply a copy of an old engraving *in line*, in which there is absolutely not a particle of half-tone. Moreover, on comparing the copy and the original, we find that the lines are much thicker and coarser in the former—in short, they look very much as if they were lithographed, a fact which, taken with the reversal in position, appears highly probable. We are also credibly informed that an able chemist has very carefully tested a print for oxide of chromium, not a trace of which he can detect, and taking all these circumstances into consideration, we are of opinion that the assertion of the proofs issued having been obtained by Mr. Pouncy's process is not made without some *arriere pensée*—obtained by *a* process of some kind by Mr. Pouncy, though not by *the* process already claimed and published by him. This is a matter that we think calls for some distinct and unmistakable assertion from Mr. Pouncy. Carbon prints they are no doubt in one sense, but we believe them to be also *lithographs*.

ON COLLODION FOR THE DRY PROCESSES.

By T. F. Hardwich.

[Read at the Meeting of the London Photographic Society, January 3, 1860.]

In the first attempts to prepare a collodion suitable for dry processes it was found that there were advantages in making use of materials like rotten cambric, shreds of filtering paper, old lint, and other like substances in which the cellulose has undergone partial disintegration by the action of chlorine, caustic alkalies, &c.; a pappy und broken-up structure of collodion being more easily obtainable in that way than by working with the fine cotton wool as it exists in the raw material. Nothing, however, will be said in the present paper on the use of these bodies, since it is now well established that both uniformity of product and stability of collodion are, to a great extent, sacrificed by their employment; and further, that the fibre of linen, being chemically different from that of cotton, does not yield a similar quality of collodion. All must be done, therefore, with the best cotton wool, and we must look to the nitro-sulphuric acid for bringing about the physical and chemical modifications which are required.

The first experiment which gave me a clear idea of the *rationale* of producing collodion suitable for dry processes was made at the time when so much was said of Gaine's process for making vegetable parchment. It occurred to me to try how this modified cellulose would succeed in the preparation of pyroxyline, and I therefore cut a piece of paper into several slips, and floated them upon the diluted oil of vitriol for varying periods of time—five, ten, fifteen, twenty, forty seconds, and so forth, afterwards washing with water, and drying each piece perfectly. The shrinking and toughness of the paper appeared to increase with the time on the acid, and, in the case of the pieces last removed, there was a peculiar jelly-like feeling whilst they remained in the washing-water, as if a chemical change had commenced. Now these pieces of parchmentised paper, on being subsequently dipped in nitro-sulphuric acid at 130°, all yielded pyroxyline soluble in ether and alcohol; but there was a marked difference in the quality of the collodions so made, for whilst the earlier samples gave a fine and tough film, the later ones—those left longest on the sulphuric acid—produced a collodion which is known as *powdery*, rubbing up under the finger like soft soap, and adhering very tenaciously to the glass. The inference was, that the parchment collodion resulted from the first or action proper of the sulphuric acid, and that the powdery pyroxyline was due to a subsequent or disintegrating effect of the same acid, which perhaps might be a partial change into dextrine. At the time, it seemed to me logical to draw the above conclusion, but facts have since come to light which show that it is not entirely correct.

Modifying Action of Sulphuric Acid.

When it became evident that the sulphuric acid exerted a modifying action in the manufacture of pyroxyline, the next question was, whether a mixture of oil of vitriol and nitric acid could be made in such proportions as to produce at once the full effect, and so to yield a product corresponding to that which is obtained when the fibre is first parchmentised, and afterwards made into a substitution-compound by nitric acid. If this were possible, the action of the sulphuric acid must precede that of the nitric acid, because, although it is easy to make the vegetable parchment into pyroxyline, yet pyroxyline, once formed, cannot afterwards be changed in properties by immersion in diluted oil of vitriol, but is protected and remains in the acid without shrinking. Therefore, in order to give the preponderance to the sulphuric acid, we make the bulk of that acid relatively greater, and in this way the parchment quality of collodion may be obtained.

If, however, the theory above propounded were correct, that the action of the oil of vitriol has two stages, a condensing and a disintegrating stage, it ought to be quite possible to prepare the porous or soapy pyroxyline in the same acid mixture which is found to answer for the parchment pyroxyline, and especially since we have it in our power to increase the action of the acids *by raising the temperature.* Experiments, however, afterwards proved that the mixture of three measures of oil of vitriol to one of nitric acid was not the best for preparing the most powdery kind of film, and that no increase in temperature or alteration in the proportion of water sufficed to give the desired result. Nothing remained, therefore, but to consider the theory afresh, and on doing so the weak point soon came to light, viz., that I had overlooked an effect of the *nitric acid,* not hitherto described, and that, to produce the pulverulent state of film in perfection *in one mixture,* the nitric acid ought to be in excess over the sulphuric. It appeared, however, that the most complete disintegration resulted when the nitric acid was brought to bear upon a material which had previously been acted on to the full extent by oil of vitriol; and this explains why, in the experiments with the strips of parchment paper, the latter samples of collodion were so entirely porous, viz., *those produced from the material which was at the verge of transition into dextrine before it entered the nitric acid.*

Preparation of either kind of Pyroxyline at will.

Having perfected the theory, it now corresponds with the experimental results, and either quality of collodion becomes obtainable at will; for if in a mixture of three measures of oil of vitriol, one of pure nitric acid of 1·45, and rather more than three-quarters of a part of water, there be immersed cotton, at 150° F., the fine transparent, tough material containing a minimum quantity of the peroxide of nitrogen is prepared; to convert which into the powdery pyroxyline we have only to dry it, and dip it for an instant in a mixture of the same acids, and at 150°, but with the proportions reversed, viz., three measures of nitric acid to one of sulphuric, in place of three of sulphuric to one of nitric, the water in the formula being omitted.

In this process a very short immersion of a few seconds suffices, and there is not much loss from solution; the pyroxyline does not gelatinise in the hot nitric acid, and can afterwards be easily washed in water; but it loses nearly all its tenacity, and flies about in dust when it is dried and rubbed by the finger. Its properties undergo an important change as regards the action of solvents, for whereas it was before unacted upon by absolute alcohol in the cold, it now liquifies into a gummy mass on treatment with this liquid. In collodion the properties differ widely from those of the parchment pyroxyline, the latter setting firmly and quickly upon the glass, but the former being nearly deficient in power of setting, so that, if the proportions of the ether and alcohol remain the same, when you allow five seconds in the one case before dipping the coated plate in the bath, sixty seconds would be required in the other. The parchment pyroxyline forms a somewhat opalescent film on dipping in the bath if the collodion be only moderately iodised, but the powdery pyroxyline produces a dense and creamy film under the same circumstances. If these films be washed with water and dried, the former has a varnished appearance, and may be rubbed with the finger without injury, but the latter is lustreless, and seems to exhibit the iodide upon the surface rather than in the substance of the film. When the sensitive plates are washed with water, and reared upon blotting-paper to drain, the parchment collodion soon assumes a condition in which it is not easily wetted, but the pulverulent film remains without much change, and a solution of albumen or developing fluid flows quite up to the edge, without receiving any check.

Although the effect produced upon the pyroxyline by the second treatment with hot nitric acid is so remarkable, we cannot suppose that any fresh peroxide of nitrogen is imparted to the fibre; three measures of nitric acid of 1·45, when mixed with one measure of oil of vitriol, produce a weaker nitro-sulphuric acid than is usually employed in the manufacture of pyroxyline, as may be proved by the immersion of cotton wool. The wool is rendered soluble at a temperature of 150°, but the film becomes cloudy on drying, and the pyroxyline itself burns in the manner of the compound made in weak acids. It dissolves also in hot glacial acetic acid, a property which Mr. Hadow mentions as peculiar to the weakest of the two substitution-compounds available for photography. This pyroxyline, which is made in one acid only, does not however correspond exactly to the other, prepared, as before said, in two different mixtures, although the state of dilution of the nitric acid in the two mixtures is nearly the same; for not only is that which has been acted upon by the oil of vitriol in addition to the nitric acid more broken up, but it yields a very limpid, structureless collodion, which adheres firmly to the glass.

Effects Contrasted.

We now pass on to examine the action of these collodions in the dry processes, taking in preference those of Taupenot and Fothergill; and I may mention that the majority of my experiments have been made with the Fothergill process, inasmuch as the plates are readily prepared, and show very characteristic differences in development. It was stated by Dr. Norris, in his early papers on the dry process, that a powdery structure of collodion allowed a ready penetration by liquids, and so favoured quick development. This may be true to a certain extent; but, in my own experience, I have found that energy of development depends much upon other causes independent of physical structure. On comparing the horny parchment collodion with that in which the film is made porous in the mode previously described, it is evident that both yield feeble images when newly iodised, but that the powdery collodion does so especially; not that this image develops more slowly — on the contrary, it comes out rather rapidly, but it has a peculiar *grey tone,* such as would be produced by nitric acid in the bath. This metallic aspect of the image depends upon the pyroxyline, and has nothing to do with imperfect washing or impurities in any form, which should be carefully guarded against in an investigation like the present. The weaker the acid, and the more powdery the film in consequence, the worse the defect, and, in reflecting on the cause, I was led at length to attribute it in part to the peculiar manner in which the iodide is precipitated in a film of this structure, for on one occasion the whole picture dissolved off into the fixing bath, leaving the collodion intact upon the glass, thus rendering it evident that the iodide of silver was not imprisoned by the pyroxyline in the usual manner, but simply rested upon its surface. To overcome this, the same pyroxyline was dissolved in a mixture consisting principally of ether, with only a small quantity of alcohol in the absolute state, and iodised with the cadmium compounds in preference to those of the alkalies. By this proceeding a more contractile film was obtained, which bore rubbing without losing its iodide, and on trial it was found that the intensity of the image was decidedly increased, a brown tone having taken the place of the grey.

As the question of colour and intensity of image is of importance, I shall not leave it without making a few more remarks. Why would the fact of the iodide of silver resting merely upon the surface of the film in the case of the powdery collodion be calculated to lessen the density? Probably because the pyroxyline made in the way which I recommend is not altogether inert to the salts of silver, but has somewhat of that action which we find possessed by albumen and many other organic bodies, of increasing the intensity of the developed image. This position I am quite able to maintain; and if we allow it to be true, it suggests the importance of having the iodide *in* the film as well as upon the surface.

We now pass on to consider the effect of keeping the collodion for a time in the iodised state before using it and I may mention that in the experiments a portion of *bromide* was associated with the iodide, not only because it has a more decided action in carrying down organic matter, and fixing it upon the film, but also because the use of bromide in the dry processes does not retard the development or make the image metallic, as it does in the wet. The bromide and iodide of ammonium and cadmium in the proportions used for positive collodion form a mixture very proper for the purpose.

The horny collodion newly iodised is extremely sensitive in Fothergill's process, but the image develops somewhat feebly, and with a long-focus lens in a subdued light there would be a want of contrast. This condition of collodion does not allow of too much washing before the albumen is laid on; otherwise the above-mentioned defects increase and the development becomes difficult to manage. Old iodised collodion differs in this respect from new: there is more decision and contrast in the picture, and supposing the preparation to be in a certain state, the plate may be washed rather freely with water previous to the application of the albumen, without interfering much with the intensity. This, therefore, is the point to which my attention was directed,

Organic Decomposition.

Whatever be the exact nature of the change which takes place in collodion after iodising with the alkaline iodides, we cannot doubt that in its essential features it consists in the pyroxyline displacing a portion of the base, and in some manner neutralising it. We therefore strive to imitate this change by adding a portion of free alkali to the collodion; and, as far as my own observations extend, the effect of all the alkalies and alkaline carbonates is nearly the same, photographically speaking. If there be a difference, it is rather in point of time and in rapidity of action than in any more essential particular.

Taking a sample of the horny collodion, made as before described, I add to each six drachms, two drachms of absolute alcohol in which has been dissolved a quarter of a grain of pure potash free from carbonate. The liquid immediately becomes ropy, and, with a less proportion of alcohol, semi-gelatinous. In a very short time, however, the ropiness goes off and the collodion is then rather more limpid than previously to the use of the potash. At this stage, a few drops of an alcoholic solution of nitrate of silver, added to a small portion of the collodion in a test tube, produce a *white* turbidity. If the cloudiness should be white at first but afterwards assume an olive-brown tint, a portion of the potash still remains in the collodion in a free state. Perhaps the safer plan will be to allow the action to continue for twenty-four hours, after which the precipitate produced with nitrate of silver will be quite white, and it then remains only to dissolve in each ounce five grains of iodide of cadmium and one grain of bromide of ammonium. If these proportions should produce *a blue film*, to which there is always a tendency in collodion having undergone decomposition, they may be increased.

The photographic properties of collodion modified in this way are very remarkable, and, on making trial of it in the dry processes, we see at once that an important change has been produced. The tendency to active development is so strong in Fothergill's process, that it matters very little in this respect how far the washing is carried before putting on the albumen; for, even if the free nitrate of silver be fully removed by copious treatment with distilled water, there is no difficulty in obtaining a dense picture. In the oxymel process, the plates develop with a bloom and ruby red colour, like wet collodion, and are in danger of running into red solarisation. I notice also a clearness and brilliancy in the image, such as usually accompanies a state of film giving intense development; the action of the reducing agent seems so strongly determined towards those parts of the film which have been touched by light that it expends itself, and hence the shadows are preserved in a state of transparency.

There is one objection to the use of alkali in the manner now advised, viz., that the collodion is rendered very tender. The state produced cannot properly be called *powdery*, a more correct term would be *rotten*. If ammonium compounds are afterwards used in iodising, the film, already weakened as far as it will bear, sometimes gives way, whilst, if cadmium salts are substituted, the adhesion to the glass is lessened and the collodion wrinkles during development. This tendency may be overcome by applying a preliminary coating to the glass, after which the working of the collodion is everything that could be desired. Those who are conversant with the peculiarities of the different kinds of collodion employed in the wet process will readily understand that the state of film now under discussion sometimes fails in rendering the half-tones, and that a hard quality of picture may be produced, unless the proper conditions are understood.

Before passing on to consider further the chemical nature of the changes which take place by the action of alkalies on collodion, it may be well to observe how cautious we should be in recommending any new step in photography without stating all the conditions. The addition of potash, for instance, is a most hazardous proceeding, and one which may bring disappointment. The mode of preparing the pyroxyline must be taken into account, since some kinds are much tougher than others, and will resist a larger quantity of alkali without becoming limpid. This I show by taking three kinds of collodion — *a*, from parchment pyroxyline — *b*, from cotton wool immersed in hot and weak nitric acid, with minimum of sulphuric acid — *c*, from pyroxyline made out of calico. On adding a similar quantity of alcoholic solution of potash to each, the first becomes glairy and subsequently liquifies to the proper consistence, turning at the same time slightly yellow. The second remains colourless, and precipitates a thick white substance, above which floats a limpid liquid almost free from dissolved pyroxyline. The third behaves differently from either, being liquid from the first, and not passing through the ropy stage.

The action of potash upon pyroxyline is decidedly complex, and, although Mr. Hadow has interpreted it under certain conditions, it does not appear to me that the reactions are the same when the alkali is employed in a minute quantity and at a low temperature, as I advise. One thing, however, is clear, that, under all circumstances, *nitrite* of the base is formed, and indeed I have seen definite crystals of nitrite of potash in residues of iodised collodion after fourteen months' keeping.

An alkaline nitrite, such as that of potash or soda, precipitates a white compound with nitrate of silver, and this substance is only sparingly soluble in water. Therefore, if we suppose a collodion to contain a nitrite in addition to iodide, the film, after removal from the bath, may be expected to bear a very large amount of washing without entirely losing its soluble silver salt. The effect of nitrite in the *wet* process is to accelerate development, and to increase the contrast between the extreme tints. I find that it acts in the same manner in the dry process; and hence it may prove of service in some cases.

Modifying Action on Chlorides.

Collodion containing nitrite, even to saturation, does not produce the same decision of image as that to which potash has been added. This I attribute in part to the fact of *organic decomposition* of the pyroxyline being produced by the potash, which renders it more difficult to wash out all the soluble silver salt. The subject is a difficult one, and needs more investigation, but I will mention a few facts which bear upon it. There are organic substances which produce no precipitate in solution of nitrate of silver, and yet can be shown to combine with it in a loose and ill-defined way. One of these bodies is *gelatine*, as the Committee which reported on the subject at the late meeting of the British Association has shown. If a sheet of gelatine be dipped in a nitrate bath, no subsequent washing will altogether cleanse it from the nitrate of silver; on the other hand, gelatine will withdraw nitrate of silver from its aqueous solution, and appropriate it to itself. The substance produced may be termed "gelatino-nitrate of silver," and one of its properties is, that it has the characteristic bitter metallic taste, but gives no precipitate with a minute quantity of chloride of sodium. I find also that *powdered gum-arabic*, on being digested in alcoholic solution of nitrate of silver, retains some of the nitrate most obstinately; for if the gum be dissolved in water (after repeated boiling with fresh portions of spirit until nothing more can be extracted), the solution has a strong bitter taste, and remains clear for a time on the addition of chloride of sodium. A third experiment was conducted as follows:—pyroxyline of that kind which has been fully acted on by the sulphuric acid in the process of manufacture, and which the experience of photographers shows to give an unusually intense image in the negative, was soaked for one hour in an alcoholic solution of nitrate of silver, in the dark: it was then washed very carefully in about twenty changes of distilled water, the washing being continued long after all traces of free nitrate of silver had disappeared; nevertheless, this pyroxyline, on being dissolved in ether and alcohol, gave a brown turbidity with hydrosulphate of ammonia, and on being treated with salt remained nearly clear at first, but afterwards became slowly opalescent.* It must be confessed that the above experiments are, with the exception of that in which gelatine is used, of an extremely delicate nature, and could not safely be depended upon if taken alone; viewed, however, as corroborative of other undoubted facts, they are interesting, and since the photographic and the chemical results tally so exactly with each other,

* A pure solution of nitrate of silver throws down a precipitate immediately, with chloride of sodium; but when these organic substances are present, either no precipitation whatever occurs, or the liquid remains clear for a time and afterwards becomes gradually opalescent. In the same manner, collodion prepared from that kind of pyroxyline of which we have been speaking may contain a weighable quantity of chloride of cadmium, and yet on dipping in the bath no precipitate may be produced, the film remaining clear and transparent.

we may safely affirm that, although pyroxyline is usually viewed as indifferent to salts of silver, yet that there are some varieties of that substance which are more or less organic in their reactions; and, further, that any sample of pyroxyline, after undergoing partial decomposition by action of alkalies, will abstract a portion of nitrite of silver from the bath, independent of the presence of nitrite, chloride, or iodide. Pyroxyline, in this state, takes its place as the lowest member of that class of photographic substances containing albumen, &c., all of which are useful in processes where the plate is washed with water previous to its exposure in the camera.

At the outset of this investigation I had hoped to perfect a method of purely dry collodion without any preservative substance applied to the surface of the film, but at present I am not so sanguine of being able to do so. The principal defect of Fothergill's process is the slowness of development, which appears to be due in part to the film drying up, and not recovering its porous condition on being wetted. Gum or gelatine prevents this, for, although the film shrinks, as before, on drying, yet when water is applied, it returns to the spongy or villous state which it had on first leaving the bath, and the development is accelerated. The experiments which I have made confirm all that Dr. Norris has advanced, but they lead us a step further, for it is now impossible to deny that these preservative substances have a chemical as well as a mechanical action, and that the colour and general aspect of the image will vary with the particular organic substance which is selected.

OBSERVATIONS ON THE NATURE OF THE VARIOUS KINDS OF COLLODION.

By Mr. Eliot.

[Read at the Meeting of the London Photographic Society, January 3, 1860.]

Although I have not had much experience in the various dry processes, having only tried them during part of one season, I found, from the uncertainty of working in the dark, the consequent loss of time was more expensive than the hire of a boy to carry the few extra things required for the wet process; yet, having given my attention for some time to the manufacture of collodion, I may be allowed to say a few words on the chemistry of this most useful article.

Collodion, then, although it is susceptible of an infinite number of modifications, from variations in the acids and their temperature, proportions of the solvents and the iodides employed, yet appears to me but to exist in three distinct forms:—1st. The hard horny film, with a glazed surface, in which the iodide of silver is imprisoned, so that neither the light nor the developer can penetrate, giving, when freshly iodised, a weak picture all over, and after it has been kept some time, intense high lights and weak middle tints, with almost any lengths of exposure. This sort is totally unfit for any description of photography.

2ndly. The extremely porous film produced from old rags, paper, &c., exposed to acids at a high temperature, but which Mr. Hardwich has shown this evening can be formed by a more certain and uniform process. In this film the atoms of iodide of silver are in close contact, and adhere together something similarly to the particles of the iodide precipitated in a glass measure, or better still, to the chloride, which, when allowed to settle down in the dark, and is then exposed to the light, little more than the surface is acted on, and consequently it will only give a weak picture. I shall return to this variety again presently, when I have finished with the next and last.

3rdly. The extremely gelatinous and slightly porous film. This is made by the first process of Mr. Hardwich—namely, by exposing the best cotton wool at a moderate temperature to the mixed acids, with excess of diluted sulphuric acid, then dissolving with as large an excess of the strongest alcohol as possible, and iodising with mixed iodides of cadmium and potassium. It is a singular fact, which has before been noticed, that the iodide of potassium, which alone is sparingly soluble in strong alcohol, readily dissolves when the two salts are triturated together before being put into the spirit, or the cadmium salt first dissolved, and the powdered potassium salt afterwards. The reason is, I believe, that a double and more soluble salt is formed. The film from this collodion is in a more expanded state, and the particles of iodide are separated similarly to the particles of sand in a new sponge, which to the touch feels gritty everywhere, but when washed out are in a very small proportion; consequently, with this kind of film the light can penetrate, and it gives a more intense picture. I am aware that some operators find a difficulty in coating large plates with this kind of collodion, but I think it is due to their method of manipulating.

I have seen some persons, directly they have covered a glass, pour off the collodion, and tipping the plate into a vertical position, hold it so, merely rocking it from side to side, until the collodion has set, consequently the collodion drags and sets in ridges, disintegrating the film, and giving the iodide a granular appearance on the lower half of the plate; instead of which, if the plate be tipped at a low angle not more than forty-five degrees and *gradually* lowered, and as the film sets, running the finger, or, better still, a roll of bibulous paper along the edge, a ridge of not more than one-eighth of an inch will be left, which will be lost in the slide. I do not mean to say the same thickness of collodion should be used for small as for large plates, or that the season of the year should not be taken into account; but it will be found the nearer the collodion approaches to this state the better it will be for all wet pictures. The proof of a good collodion I hold to be this: that when under-exposed it will give a weak impression all over; with more exposure, one a little stronger, and with sufficient exposure at least approaching to the contrast of nature, the middle tints getting stronger, while the high lights remain the same; with over-exposure universal solarisation, that no matter how long it has been iodised, it will work still in the same manner, only requiring longer exposure. A bad collodion, on the contrary, gives only a weak picture when newly iodised; when older, strong high-lights which a longer exposure only renders more opaque; and with weak middle tints, never with any exposure getting much stronger than a positive.

I now return to the porous collodion. It appears from what I have already said, and from Mr. Hardwich's experiments, that even this is not fit for the dry process, for unfortunately the more gelatinous is the film, the more it shrinks in drying, and is less able to recover itself afterwards for the development. Dr. Hill Norris's process is not so bad in this respect as Fothergill's, but the plates are much more difficult to prepare and dry evenly; they are also much more liable to blister, but then they expand better afterwards and develop more readily. I think a mixture of the two, or the addition of two ar three grains of gelatine to the albumen of Fothergill's might be an improvement, and cause the plates to develop more quickly. It is in consequence of not readily producing intensity that Mr. Hardwich has been obliged to bring about a decomposition of the pyroxyline with potash, forming an organic salt with that alkali to afterwards act on the silver. It has been doubted by some, whether such salts, as albuminate of silver, &c., do exist at all, and whether they are not rather the mere imagination of some chemical brain: that such do exist I think can be easily proved. It was only at the close of the last session of this society, that we were all startled by a gentleman, well known as a manufacturer of first-class chemicals (Mr. Williams), announcing that in distilling the residues of old collodion he had found a large quantity of oxalic acid, most likely in the state of an alkaline oxalate, which he separated by decomposing into oxalate of lime; but our wonder will cease when we reflect that all the organic radicles, such as amide, oxamide, acetyle, &c., consists of carbon, oxygen, and hydrogen, which we have in pyroxyline, with the addition of nitrogen also, and which are liable to be found on the decomposition of the unstable materials of which collodion is composed. A case in point will illustrate the part an organic element can take in a process. In a portrait establishment where I was lately at work, we endeavoured to obtain greater intensity on plates developed with iron, by coating the plate previously with albumen, by the plan of Mr. Law. At first it did not promise much success; but after a few days we were surprised to find a very great increase of intensity, fully equal to that obtained by pyrogallic acid: in a few days after the bath caused fogging all over the plate, and a new one was prepared, when the result was precisely as before, the intensity only appearing after the bath had been in use some days. Happening to run short of coated plates, an uncoated one was used, when the result was equally good: it then struck us that it must have been the albumen in the bath which caused the effect; and to prove this, a new bath was prepared, having the white of an egg beaten up with the water of which the bath was made. This answered admirably, and some beautiful pictures were taken; but the bath so rapidly produced "fogging," that it was obliged to be given up, though with regret.

There is thus no doubt of the action of these organic elements, viz., that they not only play the part of acids and form salts, but also double salts with the iodides, bromides, &c., of silver. The study of the exact nature of collodion and its decomposition affords a fine field for the experimental chemist, but it requires intense

perseverance; for when we think we have grasped a point, dozens of others start up, and what we think and hope is the end of our labours is in truth but the beginning.

ON FIXING POSITIVE PROOFS.

By MM. Davanne and Girard.

By "fixing" a photographic proof is understood the means of rendering it unchangeable in appearance and condition. To arrive at this result, the proof, upon being taken out of the pressure-frame, is submitted to the action of various solutions, which resemble each other in the dissolving action they exercise upon the argentine compounds insoluble in water, which constitute the sensitive coating.

This operation is accompanied with three different kinds of phenomena: the non-impressed parts of the proof, which if exposed to light would become quickly darkened, acquire the property of remaining colourless; a change of colour always takes place in the proof, and the intensity of the tones of the proof is frequently weakened.

From these three points of view the fixing, to be perfect, should present clear and definite qualities.

1st. The fixing agent must remove from the paper all the sensitive substance that has not been acted upon by light, so that the subsequent action of light cannot modify the effect obtained.

2nd. It must not leave upon the proof any substance capable of acting either immediately or subsequently on the substances of which it is composed, or of altering their various proportions.

3rd. It must exercise no action upon the colourless portions; or, at least, if it attacks the coloured parts it must do so only very feebly, and preserve all the delicacy of the half-tones.

A small number of substances are successfully employed with this object; the value of each under these three points of view will be examined in succession, after endeavouring first to establish the theory of fixing itself.

Theory of Fixing.—When a proof is removed, after exposure, from the printing-frame, it usually appears covered with rich purple and violet tones, formed of different substances, the nature of which has previously been made known. They are—free chloride of silver, free nitrate of silver in excess, upon which the light has not acted, and which consequently does not belong to the coloured parts of the proof. There is also metallic silver, and also that argento-organic compound of variable colours the influence of which is so great in the production of a proof.

The different nature of these four substances causes them to play very different parts when submitted to the different fixing agents. The first two undergo, under the influence of these agents, certain actions, the nature of which will be explained, but which ultimately result in a complete solution. Chemists are all agreed upon this point: the fixing agents remove the unchanged salts of silver. But there is not the same harmony of opinion as to the parts the fixing agents play in connection with the coloured portions of the proof. This disagreement may be easily explained.

The operation of "fixing" is in fact accompanied by a remarkable fact well known to all photographers. At the moment the proof is immersed in the fixing solution, whatever it may be, it is quickly deprived of its violet tint, which is changed into a brick-red colour or an orange-red, varying according to the fixing agent; but all differing clearly and strikingly from the original tint of the proof.

Various theories have been proposed to explain the nature of this change. The first is, that the proof is formed of sub-chloride of silver, Ag^2 Cl., which the fixing agent decomposes, and transforms partly into soluble chloride of silver, and partly into metallic silver which forms the proof. This theory is not tenable; for we find on the one hand that the positive proof does not contain sub-chloride of silver, while on the other it appears difficult to admit that the metallic silver precipitated can vary, not in the quality of its tones, but even in their nature.

When it was understood that, among the organic matters constituting the sheet of paper or its coating, there was one which influenced the result, a basis for ingenious theories was sought for in the modification it experienced; but they were not confirmed by experiment.

By some it was thought that the fixing agent decomposed the sub-chloride of silver, setting the silver free, and thus uniting with the organic matter formed the coloured combination comprising the proof. This modification of the first theory is no more admissible than the theory itself. For, 1st, there is no sub-chloride of silver on the proof. 2nd. The argento-organic combination exists before the fixing agent has intervened, when the light alone has acted. In fact, the coloured precipitate formed under the influence of the luminous action in a solution containing chloride of silver, nitrate of silver, starch, or gelatine, contains the organic matter insolubilised even before it is submitted to the action of any re-agent whatever.

Others say that the argento-organic combination exists before the action of the fixing agent; for according to the nature and strength of the sizing, so will be the colour of the proofs when removed from the printing-frame; but under the influence of the fixing agent the combination is destroyed, and metallic silver is set free. Like the other two theories, this also is incorrect; for, as we have shown, the argento-organic combination ***still exists after the action of the fixing agent;*** for the precipitate, fixed and well washed, still contains organic matter. On the other hand, the proof taken upon unsized paper, containing only metallic silver, is *grey* after it is fixed, and not *red*, as it would be if the silver was in presence of sizing. Therefore the organic matter exists in combination with the silver.

These theories, therefore, do not really explain the marked change of tint which characterises the action of the fixing agent. We must seek the explanation of this phenomenon in quite a different direction.

When we consider that if the image consists of metallic silver, the latter serves only as a canvas or support to the picture, and constitutes as it were a flat tint, upon which the argento-organic material groups itself in vigourous coloured tones, we are led to seek in a modification of the latter the cause of the change in tint produced by the fixing agent. Now, if we consider the nature of the fixing agents employed—hyposulphite of soda, solution of ammonia, cyanide of potassium, &c.—we remark that they all possess an alkaline reaction. We also know that the alkalies have the property of making the various substances employed in sizing swell up, or hydrating: this is particularly the case with starch. Starting from this point, we are led to think that from the moment of immersion in the fixing solution the latter exercises an alkaline reaction upon the sizing, making it to swell, and causing the argento-organic combination already formed by the action of light to undergo a hydration which energetically alters its colour. It is understood that a chemical hydration, and not merely a moistening, takes place; for the new compound thus formed possesses a peculiar colour, which is not changed by drying.

If this hypothesis be correct it can easily be proved. It is easy to find in steam from boiling water a substance which, incapable of effecting any chemical change upon the salts present, nevertheless can exercise the same action upon the sizing as an alkali, in causing it to swell. Upon exposing to the steam of boiling water a violet proof taken upon paper sized with starch, we see it instantly take the red tint which it acquires when immersed in a solution of hyposulphite of soda or of ammonia. Plunged into boiling water it experiences the same change; but immersed in cold water it undergoes no sensible alteration, for cold water does not cause starch to swell much.

Experience proves the truth of these facts. A proof taken upon paper sized with starch does not change much in tone when taken out of the frame and immersed in cold water; but it immediately assumes a red tone if it is plunged in boiling water, or simply exposed to its steam.

This theory is also confirmed by many observations. If the starch becomes hydrated only under the influence of warm water, gelatine we know is at length hydrated under the influence of cold water. Proofs taken upon English papers which are sized with gelatine become red when left for some time in cold water. Gelatine therefore plays the same part with cold water that starch does with hot.

Besides, we are satisfied that all the salts that have a feeble alkaline reaction, such as phosphate of soda, borax, &c., act in the same manner as the ordinary fixing agents, but with much less energy.

From the facts stated the theory of *fixing* is established in a manner that assures us of its correctness and certainty. The fixing agent dissolves and removes the silver salts, chlorides or nitrates, which are in excess on the paper. It exercises no action upon the metallic silver, if employed in what we may call a normal manner, that is, during a time and in a state of concentration that none of the accessory reactions we shall describe hereafter can take place. Lastly, under an alkaline influence it causes a prompt change of tint of the sizing, due to hydration, and consequently of the combination the latter forms with the silver.

A direct experiment will clearly show in what manner the argento-organic matter swells, hydrated under the influence of the alkalies. If we collect the matter deposited by a mixture of chloride and nitrate of silver dissolved in solution of starch, and if after being fixed it is left to become reduced by dessication in the open air to an elastic metalloid material, and mix it with any fixing agent, we see it increase in bulk, becoming at least double in volume, while at the same time its tint is modified. Hydrated for the first time by the fixing, this material was partially dried; but the second contact of the fixing agent made it resume its swelled state.

(To be concluded in our next.)

THE POSITIVE COLLODION PROCESS, WITH SOME REMARKS ON THE ALABASTRINE PROCESS.

By G. Wharton Simpson.

(Concluded from our last number.)

FIXING THE IMAGE,

As it is generally called, or removing the unaltered iodide of silver, is better effected, in the positive process, by means of cyanide of potassium than by hyposulphite of soda, as there is sometimes danger of the picture acquiring a brown tone from sulphur, when the latter is used. Cyanide of potassium is also more soluble, and consequently more easily removed by washing, than hyposulphite of soda. The strength is somewhat unimportant, provided that its action is not so rapid as to attack the half-tones of the picture before it can be rinsed from the surface. From five to ten grains to the ounce of water will generally be sufficient to remove the iodide in ten or fifteen seconds.

After a thorough rinsing, I prefer to dry the picture by the aid of heat. Not only is it more quickly out of harm's way from dust, &c., but in many cases, I am disposed to think, the tone is better than when left to dry spontaneously.

The picture is now completed, and ready for such finish, by backing, varnishing, colouring, &c., as may be determined on.

In regard to backing, as a general rule I object to black varnish for the purpose, as it most frequently very much degrades the tone of a picture, one of the chief faults of which is that it is already too low in tone, certainly lower in tone than any other class of picture. It generally renders the whites grey, lessens the transparency of the shadows, and detracts largely from any atmospheric effect there may be in the background. Velvet, either black or of some dark colour, such as maroon, I prefer. There are cases in which black varnish may be used to gain additional depth on some parts of the picture, using velvet for the remainder. If black varnish be used, it should never be applied to the collodion film: where that is done, I regard the picture as ruined.

In regard to the kind of transparent varnish to be used on the collodion film it is much a matter of taste. To the majority of those heavy-bodied varnishes which coat the picture with a thick glazy layer of gum I have personally a great distaste. Even when freshly applied they lower the whites; and when, as is universally the case, the gum has become yellow with age, the pictures, especially if uncoloured, present a sorry sight. I prefer a light-bodied varnish, which, whilst enriching and giving transparency to the blacks, leaves the whites almost, if not entirely, as dead and white as before varnishing. In any case, I think it wise to select a good varnish made by a person whose business it is to manufacture such things. Amateur varnish-making I regard as a great mistake.

In regard to colouring collodion positives, tastes differ. For portraiture — and collodion positives are rarely used for other purposes — I think the presence of colour little short of a necessity; and the application of *good* powder colours with anything like skill often converts a ghastly, repulsive effigy into a life-like satisfactory portrait. The colours should, however, be good, and some judgment and skill used in their application, otherwise that which was simply unattractive becomes disgusting.

I should have liked to have said something of the management of light, position, &c.; but as these appertain to the more extended question of portraiture generally, and belong in no particular sense to the positive process, I must not enlarge on the subject. I will simply refer to the advantages, in regard to artistic effect, to be gained in lighting the figure by one principal light, and not by the diffused light of a glass-house all round the figure. I prefer to have one side of the figure in shadow, regulating the amount of reflective light by the position of a white screen. The background, I think, should be quite plain, without objects of any kind introduced. This, if necessary, can be best done in colouring. A white background should be carefully avoided, as well as one too dark. A screen coloured in distemper with a mixture of black and white, or brown umber and white, gives an excellent background. If it be preferred, a light near the head of the sitter may be introduced on the backgrouud, and, if properly managed, gives relief and atmosphere to the picture.

THE ALABASTRINE PROCESS.

I must now say a few words on the alabastrine process; but as the manufacture of the preparations used involve a trade secret, in the maintenance of which there are other interests than my own, I must not enter into the subject. My remarks must, therefore, be brief, as I regard it as a violation of the privileges of meetings of this kind to make use of them for trade purposes. I will briefly refer to the characteristics of the pictures, and to the manipulatory details of production. In the meantime, I hand for inspection specimens, uncoloured, coloured, and coloured as non-inverted coloured positives.

A vigorous good positive having been produced, slightly under rather than over-exposed—I prefer the first-named of the developers, already mentioned, for the purpose — the picture, after fixing, must be very thoroughly washed, and sufficient of the alabastrine redeveloping solution to cover it is then poured over the picture. It is then placed on a levelling stand and left for a sufficient time, which may be from a quarter of an hour to an hour, depending upon the class of picture and the temperature. Its completion is determined by the whites of the picture having obtained their utmost purity. There is not much danger of the solution remaining too long; but there is danger in removing it too soon. In that case, not only is the full beauty not obtained, but there is also a danger of subsequent discolouration.

I may here remark that I remember your excellent chairman, in a very kind notice of a little work of mine—"The Photographic Teacher"—took exception to the phrase "redeveloping solution." That name was given really to express the idea of further development, as in many cases latent detail, before invisible, is rendered with beautiful delicacy by the action of the alabastrine solution.

The picture having attained its greatest vigour, is to be thoroughly washed and dried, it is then ready to receive the varnish prepared for the purpose, which gives richness, depth, and transparency to the shadows without in any degree lowering or impairing the whites.

The chief distinction in result between the alabastrine process and the simple process of bleaching by the bichloride of mercury, which latter some persons are in the habit of confounding with the former, is the absence in the former of the blue coldness which is the general characteristic of pictures bleached by the latter means; and the production in its place of pure whites combined with great vigour and relief.

An important feature of pictures produced by the alabastrine process is the facility with which they receive powder colours, and the brilliant effect which may consequently be produced on pictures of such pure tone. Another important feature is the permeability of the film, presenting the facility for producing non-inverted coloured pictures. In these photographs the powder colours being applied on the surface in the usual way are by the application of a "penetrating varnish" made to permeate the film, thus suffusing it with colour. The picture then may be viewed on the side opposite the film, presenting a brilliantly-coloured non-inverted picture, much resembling an enamel painting. It is a peculiarity of these pictures that, although varnished with a "penetrating varnish" which is a strong-bodied protective varnish, they are in no injurious degree lowered by it, or made blue, as is the case generally with bichloride of mercury-bleached pictures when varnished. Regarding their merits I will venture to quote a few lines from an interesting article in the *Art Journal* for August last — "Many of the portraits we have examined," observes the writer, "have displayed in a striking manner the correctness of this principle of colouring the photographic portrait. With all the exquisite finish of the most perfect ivory miniature, *these* portraits possess a perfection which *those* could never reach. The delicate pencil of the sunbeam has drawn with unerring fidelity lines which no artist could describe with his pencil, consequently the texture of every part of the dress, the condition even of the skin, and the physical state of 'each particular hair' remain preserved so as to bear very high magnifying power, whilst the brilliancy of colour is given to the whole. An effect is obtained in a few hours upon these photographs which could not be reached by days of the most laborious application on ivory."

In reference to permanency, on which some question has been raised, I may remark that many of the pictures now before you have been taken nearly three years, and some of them have stood for months in my rooms, without even the protection of glass or covering of any kind, without the slightest deterioration. Properly manipulated, with proper material, I believe they are quite permanent. Without this, no photograph is permanent.

I will conclude by observing that the specimens now in your hands are coloured with Newman's photographic colours, which I have always found best either for alabastrine pictures or ordinary positives.

NOTICES OF RECENTLY PUBLISHED STEREOGRAPHS.

MR. WILSON'S SCOTTISH GEMS.

(Concluded from page 7.)

We now pass to another class of views, a series for which we venture to predict a world-wide reputation, containing some of the richest gems of Scottish scenery.

The Trossachs and Ben Venue from above the Inn (No. 24) is one of those sweet calm spots which needs only to be seen to make an indelible impression on the memory. The still waters of the lake, with its fringe of rich foliage, backed by the rugged side of the mountain, and the picturesque bit of building in the foreground, seen from between the branches of a couple of noble trees, form altogether a most agreeable composition. This is a fit precursor to another scene at the Trossachs —

The Pass of Beal-ach-nam-bo, where we get more closely face to face with the bold, dark, broken, rocky side of the lofty hills, washed at the base by the waters of the lake, which reflect the grim outlines with a softened resemblance, while some silver birch trees on the right of the spectator partially veil them.

The Upper Falls of Foynes, Invernesshire. — This is a scene of magnificent rugged grandeur; tall, grotesquely-formed rocks reaching to the top of the slide are united by a single arch of brickwork. From between the crevices in the upper parts of the rock there spring some graceful ferns and straggling creepers; through the central opening is seen another mass of rock, over which, in a single steady stream, there flows the water of a mountain rivulet, which eddies around the projecting masses of stone, wearing away and undercutting their bases. In the immediate foreground an artist is seated sketching, while an attendant is looking over his shoulder, watching the progress of the work.

Upper Fall on the Giaw-valt, Braemar. — It would not be easy to select a more perfect contrast to the preceding, amongst the same class of subjects, than the one now under consideration. Here the fall is split and broken into numerous streamlets, which glide gently down the slopes of the rounded and well-worn stones in the bed of the river. This also is spanned by a bridge; but how different to the last! this being a rustic wooden structure, whilst both banks of the stream are richly clothed with masses of vigorous fir-trees growing in wild luxuriance.

We cannot take leave of the falls without a word or two more relative to three casually noticed in our last, viz. —

The Upper, Second, and Lower Falls of Moness, Aberfeldy, which, for beauty of subject and perfection of execution, cannot be surpassed, the utmost amount of detail being united with a delicate softness yet brilliancy of effect. They are perfect *pictures* of the highest class, comprising the most harmonious union of rocks, water, foliage, and above all, *atmosphere*. We give up, in despair, the hope of describing adequately these *gems of beauty*, for such they truly are.

Fingal's Cave, Staffa. — The celebrity of this picturesque cavern would alone insure a large demand for a good illustration of it; but even if it were altogether unknown, such an one as we have before us would, of itself, be enough to render it celebrated henceforth. The cave hollowed out of the basaltic rock by the restless action of the mighty waters of the ocean, presents to the eye much more the aspect of a work of art than one of nature. The sides are formed of prismatic pillars of basalt, arranged with much regularity, while the angular peaked roof, about one hundred feet high, is composed, partly of the bases of truncated pillars, and partly of amorphous trap. The sea washes into the cave, which is between three hundred and four hundred feet in depth, though it can be entered at one part on foot, the floor being composed of the sections of the pillar-tops. The rich, transparent shadows and general artistic execution of this subject are beyond all praise.

With a descripton of a few specimens of instantaneous photographs we shall close the present notice.

Prince's Street, Edinburgh, taken from just below the Sun Fire and Life Office, the spectator looking towards the Calton Hill, presents a stirring scene of activity. It is high noon-day, the pavement is thronged with pedestrians, and the roadway with vehicles in motion, while a volume of steam from the railway station, between the old and new towns, indicates that a train is upon the point of starting. Quickly as this subject must have been taken, there is a slight blurr visible in the nearest figures, owing to their being in rapid motion, but how infinitely superior to those "cities of the dead" with which we have hitherto been compelled to content ourselves.

The Breaking Wave. — The title bespeaks the subject. A low sandy shore, and a somewhat smooth sea, relieved by the wave in the act of toppling over, and three little urchins, with trousers tucked above the knee, dabbling in the shallow water. Here again the introduction of the figures is of incalculable benefit, in an artistic point of view; for the sea itself is not so striking and satisfactory *alone* as the specimens produced by Mr. Samuel Fry, of Brighton, which we noticed in these pages some time back; but, as *compositions*, Mr. Wilson's work excels. The manner in which the light on the water throws up the figures of the boys is remarkably effective.

The Victoria Steamer.—This view is taken at low tide. A calm sea and cloudless sky are broken up by the steamer leaving a long trail of black smoke behind as she speeds on her way towards Peterhead. Riding at anchor, under bare poles, is a brigantine. A long stretch of dry sand, with a hollow patch still wet, is studded here and there with masses of sea-weed, and indented by many a foot track, whilst towards the edge of the waves are seen numerous figures, chiefly boys, watching the progress of the vessel.

Aberdeen Harbour, Twilight, is a fitting subject with which to close our somewhat voluminous remarks. The dark hulls of the vessels moored in tiers contrast with the sharp tracery of the spars and rigging, which show strongly against a sky traversed by clouds portentous of windy weather. The sun has sunk below the horizon, but still tinges with a fringe of gold the edge of a long low purple cloud that Millais would delight in painting. A scarcely perceptible ripple stirs the surface of the water, and the houses of the city are almost lost in the shadows of evening. While we watch this slide, we almost fancy we hear the "good night" of those departing towards home to rest.

It is seldom, if ever, we have before seen a collection like the one we have been endeavouring to describe, possessing so uniform an excellence of equally elevated a grade. Mr. Wilson is an artist in the fullest sense of the word, and infuses his spirit into all his productions. In conclusion, we have only to say, that the printing and general getting up of these stereographs are worthy of the execution of the negatives. Their wide diffusion will carry a gleam of sunshine into many a home.

NOTES OF A PHOTOGRAPHIC TOUR IN THE HOLY LAND.

No. XII.

Leaving Tyre in the morning, we rode on with our friends, passing Sarepta without pausing, until we reached the shore near Sidon, and here we parted from them, they going on to Beyrout to rejoin the steamer, we pausing to turn eastward into the holy land of Galilee. Hassan met us here with the tents. I wandered in the forenoon through Sidon, making a few purchases in the miserable little shops, and sat on the seashore, near our tents, all the afternoon, recalling the usual subjects of thought in such places, the illustrations of fulfilled prophecy.

I defy any man to go through Palestine with his Bible in his hand and not believe that the men who wrote these predictions, which no one can doubt were written centuries ago, were inspired of God —that Ezekiel spoke the voice of the Almighty when he said, "Behold I am against thee, O Sidon."

Of the ancient glory of the city of purple nothing remains. Along the coast, here and there, are broken tombs, masses of undefinable ruins, the solemn monuments of the accomplishment of God's intent against the city of the sea. Within the city is like all others that I have seen or described. It would but weary you to repeat the story of narrow streets, filthy bazaars, crowding Arabs, Druses, Moslems, and Christians. Perhaps the pleasantest feature of the city is the American Mission here established. I called on the resident missionaries, and was deeply impressed with their vast pre-eminence as sensible, labouring men, over the missionaries of all other nations I have seen. The English mission to the Jews in Jerusalem is—with all deference to the Lord Bishop—a humbug. It is a waste of money, labour, and intellect. On the

contrary, the American missions in the north of Syria are accomplishing wonders; and the reason for the difference is simply this—that the Americans are men of common sense, who take hold of the people in a frank and intelligent manner. They gain their confidence, teach them to regard them as friends, show them that they are the pioneers of civilisation, art, and science; and if they do not convert them, they at least stand in a position to take advantage of the political changes in the East, which all know are inevitable, sooner or later.

Toward evening I walked out into a great cemetery of the Moslems. Miserable, melancholy fields these Moslem burial-places are. But the most melancholy scenes in them are the mourning groups of women. I saw half-a-dozen of them, some here, some there, uttering those loud cries of sorrow which, in the streets and the houses, may seem mere noisy demonstrations of grief, but which have special signification in the place of graves. There was one woman here that I feared would die, so fierce was her grief.

God knows she had reason for it. The widow of a Mahommedan who has loved her husband, hopeless of meeting him ever again, forced to believe him in the embraces of the houries, within whose arms he has forgotten her, may well be inconsolable. As I approached to where she knelt, she spat towards me with a curse, then wailed aloud once more. The air rang with the cry as she threw herself down on the tomb in which her husband lay, as she had left him to be questioned by the angels. They bury their dead with open space in the grave above their heads, so that they can sit up when the angel comes; and believing that they suffer torment from the moment of death till this examination is over, they hasten the ceremony of burial, so that it always follows death in a very few hours.

As I came out of the cemetery I met a well-dressed man, attended by half-a-dozen officers, who walked directly towards me. I have not yet found out who he was, whether the resident governor or only the sheik of the village. In the party, however, was a miserable-looking fellah, a common man of the country, who was evidently labouring under strong suspicion of deserving a thrashing.

The party approached me, and the chief advanced with a respectful salutation. I returned it, and through his interpreter assured him of my profound sense of his grandeur.

He assured me of my alliance with all the Sultans of the earth. I enlightened him on the magnificence of his own ancestry.

In short, we bowed and exchanged the usual salutations, and he then proceeded to business.

This poor fellah had been caught, having in his possession a silk handkerchief, which it was suspected he had stolen from my tents. A glance at it showed me that it was John's, and he must have lost it as he rode through the town. A few inquiries satisfied me that it had been taken from him as he sat in the bazaars a few moments.

The culprit looked imploringly at me, and at length got down on his knees, and began to kiss my hands demonstratively. I obtained leave of the officer in charge to punish him as I saw fit, and he sent him down to the tents with me, where John and myself held a consultation what to do with him. Hassan recommended hanging. Hassan thinks stealing from an Howajii the blackest of crimes. Achmed, the cook, recommended the rope on his other extremity—to wit, a rapping on the soles of his feet. I detest the bastinado. John proposed to the fellow (fellah?) a chance for his life, and frighten him.

So I ordered Hassan to bring out my camera, and mount it on its tripod, which was done with due ceremony. The culprit was then tied in a chair, placed at about ten feet distance, directly opposite the lens. The poor wretch rolled his eyes in an agony of fear, his hair literally stood on end, and the perspiration rolled down his face in streams. Yellow skinned as the knave was, he was fast turning white. He evidently expected a four-pound ball through his body. I went through the necessary operations of focussing the distant landscape, leaving the culprit out of the picture altogether. With my head buried under the focussing cloth, I must, of a certainty, have been an object of terror to the uninitiated oriental; but Hassan's eye twinkled knowingly, and he performed his movements with ludicrious solemnity. When all was ready, I directed him to remove the cap, keeping my eye on the culprit. He knew the crisis was come: closing his eyes he sputtered out some foam, and kicked and wriggled to such a degree that he toppled over, chair and all, at the moment John fired his revolver in the air.

I thought the fellah had died of fright; he lay as motionless as if dead. We let him lie for about five minutes, when Hassan crept stealthily behind him, and gave him a monitory kick behind. He would have risen up, had he not been encumbered by the chair. At a sign from John, Hassan loosened the cords, set the fellow on his legs again, and told him to be off, and that if he was caught his ears would surely be cut from his head. Giving him a hundred yards start, we raised something of a war-whoop. He started like a deer. I think it probable he is running yet. The last we saw of him he was on his way to Tyre at a flying gallop, and if he kept on at that rate he must be near to Jaffa by this time.

Hassan had heard something at Demetri's Hotel, in Beyrout, about letters for us, but he could not find any. Indeed no banker would deliver them to him if there were any; but we thought it worth a day's gallop to run the chance of getting them, and so the next day we rode up to Beyrout; but we found no letters, and returned in the afternoon, expecting to reach Sarepta, and find our letters there.

We had directed our men to Sidon in the forenoon, but they had found pleasanter occupation, so that when we returned to our camp, they had but just left, and we overtook them in an hour. The night was coming on. It was manifest we should not reach Sarepta as we had anticipated, and we ordered them to halt on a slope close to the sea. Here we sat and shivered while dinner was prepared. John was in an ill-humour: I in no better. Food improved us a little. Coffee soothed the waters of our troubled minds as if it were oil, and tobacco did the rest. By nine o'clock we were in a glorious condition, and then we sung.

How we did sing! Hassan and his men looked in with consternation and horror, thinking the Pashas had gone mad. What do they know of music, poor rogues? They sometimes drone a long song or story, in a monotonous strain, but when they hear a rattling, roaring song, they dont understand it at all.

Perhaps you have heard the "Postillion" song. Perhaps you have sung it. Well, sir, we sung it; and we sung "Come, landlord, fill," and John sang "Lucy Neal," and we sung many other songs along the coast of Tyre and Sidon that night. Finally, John took up the "Piff-Paft" song of the old covenanter from Meyerbeer's *Huguenots*, and gave it in a rare style. The transition from this to Luther's grand chorale was but natural, and then, as the night wore on, we sung more quiet songs; took to hymns, in fact—dear old hymns!—to which the Holy Land was not uncongenial, which might make the atmosphere of Galilee more delicious and more glorious. Some of these old hymns are very stirring and grand, and we made the hill back of the tents echo to our hallelujahs. Then came—but why tell you what we sung? You know those dear old hymns, which voices have sung which now form part of the choir of the heavenly host.

The wind came down from Lebanon to hear us, and the sea broke on the beach with a low deep melody, in unison with our thoughts and feelings; and then we lay back on our camp beds and slept.

I give you this as a sketch of our usual evenings in the tents. Sometimes we are pretty well tired out, and sleep instantly after dinner; but generally we talk a little, and laugh a little, and sing a little. I cannot say that we do often sing quite so uproariously as on that evening.

I have taken some very interesting views in this neighbourhood of Tyre, and Sidon, and of Akra (St. Jean d'Acre). I wish I could send some proofs to you; but I must wait till I meet a traveller returning to England, and who will take trusty charge of a small portfolio.

D. T.

Meetings of Societies.

LONDON PHOTOGRAPHIC SOCIETY.

An ordinary meeting of the above society was held on Tuesday, the 7th instant. Roger Fenton, Esq., Vice-President, occupied the chair.

The minutes of the last meeting were read and confirmed.

The Right Hon. the Earl of Caithness, and Messrs. Robinson and Carrick, were duly elected members of the society.

The Chairman reminded the members that this was the night for the nomination and election of auditors, and to nominate for the council in opposition to those names recommended by the present council.

Mr. Crace proposed and Mr. Bedford seconded the motion, which was duly put and carried, that Vernon Heath, Esq., and John Major, Esq., do act as auditors.

The Secretary read a letter from M. Joubert, stating his inability to attend the meeting, and his pleasure at sending a few impressions of the intended print for the society's Journal, stating also that the want of light lately has prevented his proceeding as fast as he could have wished.

The Chairman called attention to one of the specimens.

A Member asked what was the nature of the process, and what it was called.

The Secretary stated that the proof was from an untouched photographic negative; that it was executed in printer's ink, and considered indestructible. M. Joubert had called it the Phototype, and did not intend to patent his process, but purposed opening a printing establishment, and afterwards to give the details of the process to the public.

The Chairman announced that after the conclusion of the ordinary business at the ensuing annual meeting in February, if there shall be time, the Collodion Committee intended bringing forward its report.

Messrs. Murray and Heath exhibited a *Smartt's Photographic Tent*, for the purpose of explaining the improvements that have been made in it. Mr. Heath gave the following

Description of the Improvements in Smartt's Tent.

This tent is now so well known and extensively used, that it is not necessary that I should occupy the time of the meeting by explaining the principle of its construction.

My object is this—The experience that has been gained by the manufacture of the large number of these tents that have gone into use, has originated several minor improvements, alterations, and additions.

These, with your permission, I will now explain:—

1st—As to the table (for the frame-work of the tent remains much as at first designed), originally two grooved pieces were used, which, being fitted on to the ends of the table, rendered it rigid; the operation of doing this was, however, found to be rather troublesome, especially if the table had been packed up when wet by use. The two pieces I hold in my hand were substituted for the grooved-end pieces, and by this change the table is not merely increased in strength, but is much more quickly and easily put up.

Further—In the old form of table, a hole was cut of sufficient size for the insertion of an indian-rubber-cloth sink: this, while it weakened the table, made it difficult to use a developing stand. This leads me to the 2nd point, viz.—the new developing tray—an arrangement which, I venture to say, is worthy the attention and examination of photographers, on account of its efficiency and portability. It will be observed that it is made of indian-rubber cloth. has two of its sides fixed and rigid, and its two ends moveable; thus it folds up into a space little larger than one of its sides.

I will now fix the table in its place on the frame of the tent, and will merely remark, that nothing can be desired firmer and more rigid than the whole arrangement has now become.

My 3rd point is the economy of the working space of the table. A portion of it is, of course, occupied by the tray I have just described. The nitrate bath, which is one of our new glass baths, with glass tight top, is suspended from the front of the table, and rests upon a portion of the framework of the tent. By this means the space it would occupy if placed on the table, is reserved.

A contrivance was then devised for disposing of the plate slide of the camera, in order to gain the space it required, if placed on the table. This contrivance is simple and effective, and can be used for slides for various sizes, for which it provides a safe and convenient place, both before and after the exposure in the camera.

The disposal, as thus explained, of the bath and plate-holder, leaves ample space on the table for manipulating the largest-sized plates.

The collodion pourer, the developing-plateholder, the developing cups, and the water-bottle (the latter is suspended over the tray as now placed), have all special points in construction; these I will not take up your time by explaining, as they will be best understood by examination.

Nor need I describe the cover of the tent, as it will easily be imagined how this is put over the framework, and how the operator can close himself within it.

I may, however, say that it is provided with a ventilator, yellow window, pockets for cloths, and an entrance, formed for the purpose of being light-tight, like a double curtain.

This, then, is Smartt's tent in its present state; and I may remark that, having had considerable experience in its use, I consider it very successful; indeed, I believe it merely just to say that Mr. Smartt has the honour of having designed the most useful and effective tent yet made. This is so constantly confirmed by the letters of those who have them in use, that I do not hesitate to speak of its merits in the terms I have.

I will ask, in conclusion, permission to mention a circumstance, which, on the one hand, is confirmatory of the merits of the tent, and on the other, is personally very gratifying to myself. Messrs. Negretti and Zambra, some months ago, sent out with their photographer to China and Japan one of these tents; and only last night (this gentleman desiring to extend his operations), they sent off a second one. Now, I argue, that this, coming as it does from a house manufacturing so extensively their own apparatus and contrivances, is as high testimony in its favour as can be desired.

The Chairman thanked Mr. Heath for his explanation, and called upon Mr. Hardwich to read his paper.

Mr. Hardwich then read a paper entitled—*On Collodion for the Dry Processes.* [See page 17.]

At its conclusion, Mr. Hardwich stated that he had brought two test tubes to the meeting, with which he would demonstrate one of the facts noticed in his paper. It had struck him as a curious circumstance, that on adding nitrate of silver in solution to one of gelatine, which necessarily contained chlorides, being boiled down from hoofs and such-like animal substances, no precipitate of chloride of silver occurred, at any rate for some time, though a slight cloudiness might be perceived; but upon the addition of nitric acid, and the boiling of the whole, the chloride of silver was thrown down. He then exhibited the experiment, and stated that the chloride was never thrown down from the solution in gelatine, in the *same state* as when precipitated from the solution without gelatine; it appeared to be excessively finely divided, and would not settle at the bottom, but remained suspended even for twenty-four hours.

The Chairman then invited discussion upon the paper, and drew attention to about twenty large negatives of Mr. Barnes's, by the dry collodion process, with various modifications, some having preservative substances superposed on the collodion, and others used with them as a substratum on the collodion. Unfortunately Mr. Barnes was not able to be present at the meeting, but that gentleman had attached to each negative a written description of the different media employed.

Mr. Sebastian Davis was sure the meeting was indebted to Mr. Hardwich for the not merely scientific but rational and interesting manner in which he had brought forward the subject of the dry process. Mr. Davis then detailed some experiments he himself had made. He had dipped Swedish blotting-paper into a solution of *nitric acid* of s.g. 1·42, and subsequently converted it into pyroxyline: he then dissolved it in one measure of alcohol to two measures of ether; he found that it dissolved readily, and produced a film of an extremely film-like character, the very opposite to that which Mr. Hardwich had obtained of the powdery kind. He thought Mr. Hardwich had not clearly proved by the experiment he had made that sulphuric acid had the same effect upon cotton wool that it had upon paper: he said he dipped paper into sulphuric acid, and converted it into pyroxyline in one case of the tough, and in the other case of the porous kind. There was a difference between the cellulose as paper and the same as cotton wool. If the action of sulphuric acid be continued upon it at a certain temperature, it converted the cellulose into dextrine, and if continued further, into grape sugar. He thought it was still a question whether collodion of a porous character was by any means so sensitive for dry processes as one of a tougher texture.

The real principle of preparing a dry plate for taking a picture required that the developing fluid should be able to penetrate the film. Under ordinary circumstances if we take a plate with a sensitised collodion film upon it, and wash it, it will be so hardened upon drying that the developer will not penetrate into its pores. It is requisite, then, before drying the plate, to apply some substance, soluble in water, so that when the developer passes over the plate, it shall, by dissolving the preservative material, enter into the body and substance of the film, and so produce the desired effect. In Fothergill's process Mr. Davis did not think that there was a difficulty in obtaining the requisite intensity which had been alleged, and Mr. Hardwich did not state in what way he reckoned the slowness in development, nor whether he compared the dry plate with those that were wet. If Mr. Hardwich compared it with the wet plate undoubtedly it developed slowly, but Mr. Davis thought it as quick in developing as any other dry process with which he was acquainted, and regarded moderately slow development rather as an advantage, for an inexperienced operator when developing in yellow light would be almost sure to over-develop a dry plate.

He (Mr. Davis) considered the Fothergill process to be based upon a truly rational principle—that of washing the plate free from nitrate of silver, and then applying some substance which will enter into the pores of the collodion, and be soluble in water. He must confess that he met with a difficulty in the Fothergill process which he had not been able to surmount, and which he should have had great hesitation in stating but that others had found the same difficulty—that was a marbled appearance of the skies. He had made various modifications in the preparations of the plates, but had invariably found that if he used a levelling stand, when developing, without keeping the plate in motion, those marks appeared; but if he kept the plate continually in motion, he avoided those marks, but sacrificed a portion of the beauty of half-tone which the negative would otherwise have possessed.

Mr. Eliot then read a paper on *Observations on the Nature of Various Kinds of Collodion.* [See page 20.]

Mr. Hughes, without taking up precisely the line of argument which Mr. Eliot had pursued and Mr. Davis commenced, would endeavour to call attention to the exact point, as far as it appeared upon the general practical point of the dry process. The society was indebted to Mr. Hardwich for devoting his philosophical attention to the subject at this time, when the variety of processes was so great as to become almost nauseating. He thought that involved in Mr. Hardwich's paper was this point, although Mr. Hardwich had not called special attention to it. Generally these preservative agents had been considered to serve the purpose of holding the plates capable of being restored to the same condition as in the wet process; but he thought Mr. Hardwich had shown that the preservative agents, innocent and inocuous as they had been supposed to be, had other very important chemical functions, which must now be studied in reference to their action when united with nitrate of silver, forming therewith new compounds which ultimately affect the picture. Mr. Hardwich had also called attention to the curious part which the chlorides and bromides play in the dry processes, in contradistinction to their action on the wet process, retarding the actinic action in the latter while assisting it in the former. Of this fact no explanation had as yet been attempted. It was now also proved that the very agents themselves, which were merely employed to act mechanically, really act chemically as well, and that even collodion itself, under certain conditions, possessed a chemical action apart from the bromides and the chlorides.

Mr. Malone stated that Mr. Hughes having spoken in the plural *(we)*, he rose to say that he did not consider the albumen, gelatine, &c., to act singly in preventing the condensation of the film to an impenetrable condition. He thought even apart from any functions they might play in combination with nitrate of silver, that preservative agents kept the film in a moist condition. If chloride of silver were precipitated from nitrate of silver in the ordinary manner, and then boiled while it was still moist with caustic potash, it would be very readily decomposed, but if it were allowed to dry, the act of drying would alter the physical aggregation of the particles, and would therefore not readily yield to the action of chemicals. With regard to the observations of Mr. Hardwich in the latter part of his paper, with reference to the combination of nitrate of silver with organic matters, the subject was not altogether new to him (Mr. Malone), and he should have felt bound to take some blame to himself for not introducing it before, but that he could not devote himself wholly to photography as Mr. Hardwich did. Mr. Fox Talbot informed him that, in making experiments with sheets of gelatine for negatives and positives, he found that by immersing the gelatine in nitrate of silver he could get the

nitrate to unite, so that he could dry it and subsequently procure a picture. In some of his experiments Mr. Talbot had purposely placed a surface of albumen on a weak solution of three grains of nitrate of silver to the ounce. The plates so coated were dried and then covered again with albumen, and subsequently coated with syrup of iodide of iron. The surface being thus prepared, the plate was finally immersed in nitrate of silver. There was therefore a surface of nitrate of silver with albumen below all, and to that day they did not know the functions of that particular layer of silver. That part of the subject was still mysterious, and required further investigation. He thought it was Mr. Fox Talbot who opened the door in that direction.

Mr. MALONE also stated that in 1851 he took up Mr. Talbot's experiments, and added to the white of egg (which every one knew contained common salt) some nitrate of silver, and got a precipitate which he stirred in the bulk of albumen, and found it to redissolve. Of course it became puzzling, and he did not know to this moment whether anybody had accounted for that. We call a substance gelatino-nitrate, and so on, but it was usual in examining chemical bodies and salts, before giving them names, to be able to separate them in a state of purity; and it happened, unfortunately, that a large class of metallic compounds with organic substances could not be recrystallised out. Here was an inherent difficuity, which might be overcome, but how to do so was the problem. Until the substance was so solved that it could be analysed and brought back again to its exact constituents, they could not give it a name. Sulphuric acid could be prevented from yielding a precipitate with baryta by addition of alchohol; and in this way we have the solution of sulphuric acid combined with the bases of alcohol and baryta salt, which does not give a precipitate or troubled appearance. This difficulty was well known to chemists in their ordinary operations, and this part of photography was a further exemplification of that difficulty. Another point to which he would direct attention was the influence of organic matter upon the resulting colour of the proof; and in that he thought Mr. Hardwich had done good service. Pyroxyline was not a substance, as far as he could judge at present, that he could precipitate in that definite form that he could oxide of silver and oxide of lead, and other substances. Pyroxyline contained other organic substances—the elements of cellulose, combined with a given quantity of hypo-nitric acid; but by adding potash we get rid of a portion of the hypo-nitric acid, and obtain nitrite of potash. As long as they proceeded in that manner, and produced compound things with such facility, he for one would say he could not see his way out of the difficulty. It was useless for any one to say this or that collodion was the best. We should deal very cautiously, and not attach undue importance to any new recipe or statement until the whole subject was properly sifted.

Mr. HUGHES stated that it was known previously that in the Taupenot process the preservative agent did play an important part.

Mr SHADBOLT stated that he differed from Mr. Hughes in his opinion that the *special novelty* of Mr. Hardwich's paper was the recognition of the fact that the compound of organic bodies with nitrate of silver played an important part in the dry process. The truth was that the first inkling of that fact was propounded at Manchester, by Mr. Young, when he found that it was possible to dissolve out the iodide of silver from an exposed plate *prior to the development of the image*, and subsequently develop it in the ordinary way, provided that albumen had been employed as a preservative agent—in fact, that he could get this image just as readily and quickly either by fixing first or developing first; but, supposing there had been no preservative agent used, and simply ordinary collodion, if he attempted to develop *after* the removal of the iodide from the wet plate he could not get any picture. The matter was also brought forward at the North London Photographic Association at the conclusion of last season—that is, somewhere about May or June—where it was discussed; and he thought that all who took part in the discussion came to the same conclusion—that is, that it was due to the presence of a compound of organic matter and silver in some form or other. He believed that at the same meeting Mr. Hannaford had pointed out that impressions were obtainable upon iodide of silver, provided any other silver salt were also present. The matter was therefore not so new as Mr. Hughes had supposed. He thought there was some error in Mr. Davis's supposition relative to the kind of collodion which was recommended by Mr. Hughes. He (Mr. S.) did not understand him to recommend the powedery film, but merely to have stated that it *had been recommended*, Mr Hardwich preferring the parchment-like or horny film, modified by the action of a free alkali, and consequently brought to the condition which enabled it to form a compound with the nitrate of silver.

Other gentlemen who had spoken had taken up the points upon which Mr. S. had made memoranda, he would therefore conclude.

Mr. CRACE would have been happy to have heard the opinions of those gentlemen who during the last season had practised the dry process in the camera. There were several specimens upon the table in which different processes had been adopted, but they emanated from one gentleman, and it would have been more satisfactory if different gentlemen had furnished the results of their experience. There was an aspect of the matter which he thought would be attended with advantage: if instead of first of all preparing an iodised film, and then using a silver bath, there might possibly be a form of preparation combining the silver bath with the preservative agent in one. He thought Mr. Lyte specially alluded to something like that. Surely that carried out successfully would be an important step in photography, and he should be glad to hear from Mr. Hardwich whether he thought there was any possibility of obtaining such a result.

Mr. SHADBOLT stated that that very question had been already answered by Mr. Mayall some years ago. The first dry collodion plates brought before us were by Mr. Mayall using a bath of nitrate of silver in which albumen had been previously placed.

The SECRETARY stated that Mr. Barnes, who was ill, had requested him to read the following:—"The principle of obtaining dry collodion pictures proposed by Mr. Hardwich is not the one I should now even think of following. The most economical way with reference to ease of manipulation, time occupied, &c., of producing prepared plates that may be relied upon is to proceed as follows:—To coat the glass in the first instance with as delicate a coating of albumen as it is possible to obtain, drying off rapidly by the fire; to employ collodion in its most perfect state, free from decomposition; the iodising solution to be that found to work best with the wet process. I give the preference certainly to iodide of potassium used alone and not in combination with any other iodide. The plate to be sensitised in the usual way, and thoroughly well washed to free it from every trace of nitrate of silver; then washed over with a mixture of equal parts of the albumen previously used, and of the ordinary pyrogallic developing solution, and finally dried. Plates thus prepared will be rapid in action, will bear any amount of washing, will not blister or crack during development or whilst drying off. Although I have produced satisfactory results by my method of working, the process is still open to improvements—the most essential being the lessening the time of exposure, the discovery of a means of obtaining power without the use of silver in the developing solutions, and of increasing the rapidity of the development. These improvements, however, depend upon experiments connected with the wet process. I may mention that I already obtain stereoscopic pictures in ten seconds on the average."

Mr. SHADBOLT thought that to Mr. Barnes was due a great deal more credit than was given to him, for he had been the first to produce a presentable dry plate. He also stated that if a plate were coated with a thin film of albumen, and dried—afterwards coated with collodion, sensitised, exposed, and developed, that the image would be found *on the film of albumen*, as could be proved by removing the whole of the collodion.

In answer to a question from Mr. S. Davis, as to the removal of the collodion, Mr. SHADBOLT said it was very easy to remove the collodion, by rubbing it with a little pledget of cotton dipped in alcohol, without injury to the albumen, because the latter is rendered insoluble by its immersion in nitrate of silver.

Mr. MALONE said that Mr. Fox Talbot found that his albumen film would bear rubbing with cotton wool thoroughly. It was most remarkable that in Mr. Shadbolt's case they had the first film of albumen, then collodion, then the plate dipped into nitrate of silver, which was still a return to the same fact observed in Mr. Talbot's case, for the nitrate of silver goes through the collodion, and acts on the albumen below, and the image goes through collodion, and so upon that film below. So with Mr. Talbot: he had used a film of albumen acted upon by nitrate of silver; over that he put iodide of iron, and then a second dose of nitrate; and still, in spite of that, the *upper* surface had not the permanent image, and was often smurred and dirty, and it was necessary to rub that off, and the real image was on the lower film. They found, when experimenting some long time since, that a bath that had been used for dipping albumenised plates for some weeks came afterwards to be used for the French paper process, and that paper, excited in the bath used for albumen plates, gave an image in dull weather in far less time than usual. There, again, was an action which was little expected. They should have supposed that it would have retarded it. But we never succeeded in purposely making a bath with that property, which showed that they had got a great deal of work to do in all directions; and it would now be desirable to try Mr. Barnes's plates, and dip them in albumen, and see whether it increased the rapidity of his process.

Mr. SHADBOLT drew attention to the fact that he saw some pictures at Glasgow, last year, produced by Mr. Kibble, of that city, with about a twentieth part of a second's exposure upon a dry film of large size, with a single achromatic lens of six feet focus.

Mr. WATSON did not agree with Mr. Hardwich, that either the iodide of silver or the image was upon the surface. In the instance cited by Mr. Hardwich in his paper, he thought it was imbedded in the collodion, and he would engage to produce from any kind of collodion a picture that could be rubbed off entirely from the surface, but that was not iodide of silver: he supposed the nearest approach in name would be an oxide, and that he had found especially to occur in the dry processes when using too much silver in order to hasten the development; the picture was produced more rapidly, but if they touched it with their finger or a little cotton it would rub it entirely off; but with the very same collodion, they could have the image in the body of the collodion, so that when it was dry they might rub it with their finger and give it a burnished appearance. He had one or two plates there to give a proof of that. With the same collodion he had had the picture upon the surface, and, as was seen there in another plate, in the body of the collodion. He had never tried to produce collodion in the way that Mr. Hardwich advised; he had always produced it in a way almost the opposite, and he found that

instead of the washed plates being slow in development, for dry plates he thought they were exceedingly quick.

Mr. ELIOT asked whether Mr. Watson used albumen or gelatine.

Mr. WATSON always used albumen in preference to anything else, because it gave a decided firmness to the film.

Mr. MALONE thought he could clear up what appeared a discrepancy in the mind of the last gentleman who had spoken. From Mr. Malone's experience in albumen, he thought it might be explained. He exposed a film to the vapour of iodine, which produced a deep orange colour; that was immersed in nitrate of silver; by developing with gallic acid he got a negative image, which he should describe as in the film, but on developing with pyrogallic acid with nitrate of silver, he then got, piled up, an image on the surface, like the daguerreotype. That was a surface image. The change was carried on out of the surface of the plate. The silver so piled up was, of course, loosely adherent, and could be wiped off. If you use strong solution with nitrate of silver, in the first place you produce the spangles of surface silver, and then heap it up in the metallic form; and he thought, taking into account the difference of little or much silver, it would be seen there was no great discrepancy in the matter, and that Mr. Hardwich might be right, and that the collodion should contain sufficient porosity to allow the development to go on.

Mr. WATSON thought Mr. Malone had misunderstood what he had said, or perhaps he had not explained himself clearly. Mr. Malone appeared to think Mr. Watson meant that the picture on the surface could be burnished. If it were attempted to rub such a surface as that the picture would be destroyed with a mark all over it, simply because the picture was powdery on the surface; but it was when the picture was in the body of the collodion that it could be burnished.

Mr. MALONE said he made all his experiments with an agate burnisher.

Mr. HARDWICH said he had jotted down a few notes upon the remarks that had been made by the different speakers, and he would reply to them one by one. He understood Mr. Davis to ask why did not Mr. Hardwich first immerse the cotton wool in the common form, instead of putting it into a solution of sulphuric and nitric acid. Mr. Hardwich had an impression that if he attempted to lay cotton wool in the sulphuric acid it would be dissolved. It would be necessary to have a small portion of nitric acid to prevent the cotton wool from dissolving. Then Mr. Davis next asked as to penetration. Mr. Hardwich believed the penetration assisted the development, but it seemed to him the horny film would have the image more on the surface, and be more easily removed by cotton wool; therefore, although he believed that penetration assisted the development; he thought it was quite possible to develop an image almost, if not entirely, superficially. Now, was Fothergill's process a slow one? He recollected a letter he had received from a clergyman, who was a close observer, who said he had succeeded with the Fothergill process in stereoscopic plates, but not with large ones. He had an impression that it was a slow developing process, and worked with difficulty when they used a lens of a long focus and newly iodised collodion. He had never seen the water markings—he had read of them, and quite agreed with Mr. Davis that the proper way to avoid those brain-like markings on the sky is by keeping the developing solution moving, and he was inclined to hope that that did not affect the delicacy of the picture. With reference to Mr. Eliot's observations, he did not think Mr. Eliot quite entered into his views on the subject of the state of the film. Mr. Eliot communicated a process some time ago, by which he described a process for purifying a nitrate bath contaminated with organic matter by using citric acid. He (Mr. H.) found that by using citrate of soda a chemical compound was formed between the citrate of silver and the organic matter, &c., following that up with gelatine and other substances he found similar chemical compounds produced. In dry processes much depended upon having a collodion that admitted of this double combination, and he did think they must have a collodion in which the pyroxyline itself was capable of extracting some of the nitrate of silver, and then entering into some combination with a portion of the iodide—not the whole of the iodide; and, repeating what he had before said, he recommended for the dry process a collodion which for some reason or other should have that property acquired by organic decomposition of combining with nitrate of silver. He had made pyroxyline by boiling with nitric acid, and in that case he thought he obtained glucose. He had first in the film the organic compound of the pyroxyline, with a small portion of the iodide, which made it in a measure independent of the albumen. As to Mr. Hughes's remarks, with regard to the action of chloride or bromide and of iodide in the wet process and the dry, they are exactly opposite. It was known that there was a compound, the iodo-nitrate of silver; but if he tried to put it in form, and say a compound of chloride and nitrate of silver, that did not express it. He could form the iodo-nitrate, but he could not form the chloro-nitrate. He found that he had a distinct compound of the iodide with the nitrate, but none with the chloride, therefore he should expect that the chloride would act differently in the dry process. As to Mr. Malone's observations upon the change in the drying of the chloride of silver, that was a very different molecular condition, and had a great deal to do with it; and he scarcely knew how much to attribute to molecular condition and how much to chemical action—both undoubtedly played important parts. The members would see by the test tube he held in his hand the chloride of silver in suspension, and that it would not go down: had the very finely divided state of the silver in that anything to do with it? He thought what Mr. Malone mentioned with regard to chloride of silver changing in drying, had something to do with it, and hoped he (Mr. Hardwich) would always be found open to any reasonable view. Mr. Shadbolt had spoken of his (Mr. H.) using two acids: The paper which he had the honour of bringing before the meeting was a paper on the theory of the subject, and he wanted to ascertain precisely what part the sulphuric acid played, and the thing was of great importance. Last year he obtained collodion in London perfectly powdery, and the negatives were so extremely weak that it was impossible to work the collodion; the skies were insufficient, and it was thrown aside as useless, and soon after he received a letter from a gentleman at Malta, who said he had a collodion which ought to be fit for the dry process, but gave a weak negative, and he (Mr. H.) had no doubt that was made with nitric acid, and that was the reason it would not give intensity. He did not recommend the two acids—he simply wished them to be tried. Mr. Crace spoke of adding organic matter in the baths. He once used some glycyrrhizine in the bath; he got an excellent picture on Monday, and on Saturday he got a reversed action of light, and a positive instead of a negative. The organic matter must be in the collodion, and must be something which cannot be dissolved out in the bath.

Mr. Barnes said that he did not think they would succeed by the Fothergill process with larger plates than 10 × 8, and then not with more than six out of a dozen: the film would tear off when drying, after the picture was completed. There was one on the table which had curled off the plate at the time he was in the dark room washing it; he had a solution of gum there, and, touching the edge of the glass plate with the gum, that prevented it from coming away. In some instances he had seen the pictures 10 × 12, though in every other circumstance perfectly satisfactory, completely curled off the plate—just sticking to the plate in particles. The greater proportion of the negatives on the table were produced by first coating the plate with albumen; it did not matter how thin; and that was the only way, he thought, they would succeed with the dry process. He had in his hand a transparent positive, produced by Mr. Watson, and in his remarks he said it was a rapid development; Mr. Barnes admitted that if it was a positive on glass it was a rapid development, but that was a very different matter: he had always been able to get a positive in five or ten minutes with the development, provided it were sufficiently exposed.

Mr. Hardwich further said he certainly thought they ought to thank Mr. Barnes for bringing forth plates of a large size. He thought they wanted to know what process would do on larger plates as well as on those on which short-focus lenses were employed. He might take that opportunity of saying that he had always valued Mr. Barnes's work most highly. Mr. Barnes would excuse his (Mr. H.'s) saying that too many things were published without giving the reason; and it behoved an inventor, if he wished to claim the public credit of his invention, to distinguish the essential from the non-essential, otherwise others would come forward if they elucidated a point, and must, of course, have the credit of that, although the thing might have been indicated or alluded to before. In photography it was impossible to go back to ascertain who was the first inventor of many things. Except Archer's collodion and Mr. Fox Talbot's works it was impossible to say who was the inventor. He thought they must all work together, and all obtain a share of the credit. With reference to the image being in the albumen, it appeared to him that the image would be in the gum-arabic if it were upon the albumen. Every organic substance gave an image of a peculiar colour. When it was in the albumen it gave a yellow, but in gum it gave a ruby red. If he had gum at the top of the albumen, he obtained a red. He also observed that if he took a certain plate of collodion and dipped it in the bath, and coated it with gelatine, the film is not so creamy in the bath; and when he came to develop, he saw an indication in the gelatine of the image being more intense; but if he took another coat of gum, the image would be in the gum and not in the albumen. He had found that the preservative at the top was the one most likely to furnish the image—of course he only judged by the colour.

The meeting then adjourned at an unusually late hour.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

AT the ordinary monthly meeting held at Myddleton Hall, on Wednesday, the 28th ult., W. SHAVE, Esq., was in the chair.

The minutes of the previous meeting were read and confirmed; after which Mr. GOSLETT called attention to an inaccuracy that had crept into the report of the proceedings of the meeting respecting the method of flattening crown glass. *A hot iron is not passed over the surface for the purpose of removing inequalities;* but the glass is laid on a smooth stone in the kiln and exposed to a great heat; this renders it very flat, and produces what is called *fire polish.* After this, if it is to be converted into *polished flatted* crown, it is polished by hand. This glass is as good as patent plate for small pictures; but for larger sizes, say 10 × 8 and upwards, he would not by any means recommend its use; patent plate being so much flatter, and less liable to breakage in the printing frame.

The CHAIRMAN then called upon Mr. Melhuish to read his paper on the Metal Camera produced by him. [See page 5 in our last.]

A vote of thanks was given to Mr. Melhuish, and a general discussion ensued.

Mr. MELHUISH stated that he had had under consideration the expediency of using vulcanite, papier maché, or cloth, for the panels of *large* cameras, where the styles and frames were made of metal; but he doubted whether any advantage would be gained by their use, as metal could be employed so very thin that the weight would be no greater than either of the above-named substances.

Mr. LYON exhibited a camera of his own make, in which the shutter, instead of being drawn up, was made to fall forward into the body of the camera. The camera was made upon the American bellows principle, the bellows being formed of roan leather; but skiver, a thinner kind of leather would answer the purpose equally well, with the advantages of being both lighter and cheaper.

The CHAIRMAN said that in the cameras he used, and which were made by himself, the dark slide was drawn out at the side.

Mr. HUGHES exhibited a very compact stereoscopic camera. The dark slides (six single or four double) were contained in the body of the camera, with a movable diaphragm, which divides it when in use. The tripod head is fixed to the bottom of the camera: this he regarded as a great advantage in many respects, as it cannot well be lost, break the ground-glass screen, or scratch the camera in stowing away, or tear the pocket like those now in use when so carried. The slides glide into a *horizontal* groove or rabbet, constructed in connection with a light framework at the back of the camera, which framework itself is capable of being slid out vertically (like the slides in ordinary cameras) in order to give access to the interior of the camera for packing away the spare slides, &c., for carriage. The stand is in the form of and about as stout as a strong walking-stick.

Mr. HUGHES regretted that he had promised to exhibit the camera this evening, as he had already made several improvements, and others suggested themselves, so that by another month he hoped to render it the most useful and compact camera in the market.

The thanks of the meeting were given to Mr. Hughes.

Mr. SQUIRE exhibited a stereoscopic camera for taking instantaneous and other views. On the front were attached two revolving discs, similar to those under the stage of a microscope, and furnished with apertures of different diameters; these were covered by a flat shutter of metal, capable of being released by a spring, so that the two lenses are opened and closed simultaneously. The focus is arranged from the back by means of a screw; the lenses are fitted inside the camera in *wooden* mountings. The revolving diaphragms, as arranged in this camera, are not in the least in the way, and the focussing screen is hinged to the top so as to turn aside to admit the dark slides; thus there are no *loose* pieces to be lost or forgotten. The whole affair is very compact and well designed, and will, with some further improvements contemplated, no doubt prove deservedly popular.

Mr. SQUIRE also exhibited some stereoscopic views of waves.

The thanks of the meeting were voted to Mr. Squire.

Mr. W. BOLTON, of Holborn, exhibited copies of the *Amateur Indian Photographic Album.* They were greatly admired, and considered very far superior to the numbers of the same publication exhibited by him last year. He also exhibited *Stereoscopic Views in India,* by Captain Scott.

The CHAIRMAN informed the meeting that the presentation photograph would be ready for distribution at the next meeting, on the 25th January.

The meeting then adjourned.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE third meeting of the session of this society was held at the Rooms of the Literary and Philosophical Society, 36, George Street, on the evening of the 4th instant, Mr. DORRINGTON in the chair. In consequence of the season of the year the attendance of the members was unusually small.

Mr. H. Petschler was elected a member of the society.

The HONORARY SECRETARY reread Mr. Shadbolt's paper *On Lenses,* which had been previously read at the former meeting, and the discussion on it adjourned to this meeting. A general discussion took place upon the subject of the paper, particularly as to the position of the stop between the lenses.—The Secretary also read a letter from Mr. Joseph Sidebotham, stating his inability to be present, as he was going to Paris; and calling the attention of the society to the misapplication of the word "instantaneous," as generally employed in photography. A photograph taken in several seconds, or in a fractional part of a second, being both called "instantaneous." He hoped some one would be able to suggest a more correct word, and thought if our own language was deficient in such a word we might seek the aid of foreign ones.

The members thought no better or more expressive word could be used, and that the only plan to get out of the difficulty would be to state the exact period of time, either in seconds or in the fractional parts of a second.

Mr. PARRY said that Mr. C. Hebert, a member of the society, had stated that he believed the most important of all matters to be observed in the preparation of the collodio-albumen plate, to avoid blisters, was to let the collodion film set very well previous to its immersion in the bath.

It was thought by the members that this was very important, but some of them considered the baking, after the coating with albumen, was of the greatest consequence.

Mr. PARRY wished to know if anything could be suggested in the way of lightening the weight of the cameras.

Mr. MUDD said very small and light folding stereoscopic cameras might be constructed so as to go into the coat pocket.

A general discussion took place on the subject of deal, metal, and otherwise constructed cameras.

The CHAIRMAN stated that some plates he had put in a metal box were covered with red spots on developing.

Mr. MUDD also said he had noticed the same effect, but thought that in all other respects metal boxes were very good for preserving plates.

The red spots were believed by some of the members to arise from the sharp edges of the glass detaching small particles of the solder in the groovings.

Mr. WARDLEY exhibited some plates prepared at Mr. Mudd's establishment, and not developed until five months afterwards, being exposed four months before development. The negatives were handed round, and were very clear and good, showing no signs of redness from over-keeping. They had been placed in a metal box.

Mr. WARDLEY said he had not found the objection that deal boxes took away the sensitiveness of plates, as was usually complained of.

Mr. PARRY said he had kept plates in deal boxes very satisfactorily, but thought it best to varnish them.

The CHAIRMAN said he had lately obtained some of the German glasses, and had experienced much annoyance from the great difficulty of getting them clean, and the irregular way in which they were cut.

Mr. PARRY said he had found Chance's, of Birmingham, the best and the neatest cut glasses.

The CHAIRMAN exhibited several stereoscopic negatives which he had taken by the gelatine and raspberry vinegar process. They required about the same exposure as for collodio-albumen, and he thought the process was capable of producing first-class negatives as well as transparencies.

Mr. PATTERSON said he had tried the process, and liked it very much.

Mr. WARDLEY had often tried the process, and had also obtained as good results from a combination of gum and sugar; he thought the collodio-albumen process was still the best for negatives. He (Mr. Wardley) wished to call the attention of the members to a peculiarity in the plates prepared by Dr. Hill Norris, namely, that if the plates were not developed soon after exposure the image gradually disappeared. Dr. Hill Norris had admitted this fact, and recommended the plates to be developed as soon after exposure as possible. Dr. Hill Norris's plates kept very well indeed up to the time of exposure.

Some discussion took place upon the comparative merits of the collodio-albumen and the raspberry syrup process, and it was generally thought collodio-albumen was still the best.

The HONORARY SECRETARY announced that Mr. Mabley had kindly promised to read a paper at the next meeting upon *The Various Methods of Paper Printing, Toning, &c.*

After a vote of thanks to the Chairman, for presiding, the proceedings closed.

PHOTOGRAPHIC SOCIETY OF SCOTLAND.

THE monthly meeting of this society was held on the evening of Tuesday, the 11th instant.

Dr. WALKER occupied the chair.

After the minutes had been read and agreed to, the following gentlemen were balloted for and admitted members of the society:

—Mr. Thomas Pearce, Braemar; Mr. J. Stewart, Inverness; and Mr. A. Claudet, London.

The CHAIRMAN stated that at the last meeting of the council it had been determined that it should be referred to Mr. Horatio Ross to award the prizes offered by the society for the best pictures in the exhibition.

Dr. PATERSON, of Leith, who had successfully practised the process during the last autumn, then made a communication

On the Dry Collodion Process.

The dry collodion process (he said) was now beginning to occupy a prominent position in photography, not only from the effects being equal to anything yet produced by the wet collodion process, but from its being so much more portable and convenient in the field. The dry processes might be divided into two:—first, those properly so called dry processes, where no preservative had been used for the protection of the collodion film; and second, those in which such means had been considered necessary. In the first, resin, amber, gutta percha, and more lately a peculiar kind of pyroxyline, had been used in the formation of the collodion, which, upon being used in the ordinary manner, sensitised, and then worked, was said to keep for any length of time without injury. With the exception of the last, all the others had been tried by him, but without satisfactory results; and it was his distinct conviction that no collodion film would give anything but uncertain results after a time, without some preservative covering. The great desideratum in plates preserved in this way had not been that some of them by all the processes did not give good results, but that the results were not certain; that with all the care which could be bestowed on the process, out of twelve prepared plates seven or eight would turn out failures. Now, the process which he was about to describe to the meeting that evening counteracted, he thought, much of that uncertainty. The plate was coated with a certain kind and thickness of collodion; it was immersed for a given time in a bath of a *certain* strength; it was washed with a *given* quantity of water; it was then coated with a *given* strength of the most simple preservative solution; and then it was dried slowly by means of heat. By this method much more equal results necessarily followed than if the plates were washed with an *undefined* quantity of water, and with a preservative solution, which some recommended to be made acid, some neutral, and some alkaline. The Doctor then exhibited the apparatus used for drying the plates, as also some of the negatives themselves of large size, and a number of views taken by the process; and showed, as an illustration of the equality of the prepared plates, four views taken on a recent excursion to Inchcolm. The four plates were taken out of a number which had been prepared six weeks previously: only four were taken, and the results were equal in them all. The process was not new, but some modifications he had made of existing processes, had enabled him to work with a certainty which in no other process he could attain. He then reviewed at considerable length, and with great discrimination, the principal dry processes at present before the world, and stated that the one he then advocated was the following:—The plate being coated with collodion containing a large proportion of alcohol, is excited in a silver solution which is rendered acid by the addition of acetic acid.

The collodion consists of—

Sulphuric ether and alcohol, of each.........	12 ounces.
Iodide of cadmium	40 grains.
Iodide of potassium............................	40 „
Bromide of cadmium	20 „

The silver bath consists of—

Nitrate silver	40 grains,
Acetic acid	20 „

to each ounce of water.

It is then washed in a limited quantity of water, and after being dried by heating, it will keep ready for exposure; and the development is with pyrogallic, formic, and acetic acids.

Dr. Paterson's address was warmly applauded, and a vote of thanks was tendered to him.

Mr. MACNAIR stated that he had hit upon a dry process, which he thought promised to give good results. It consisted in substituting brewer's wort for the various agents used in preserving the plates. In conjunction with Mr. Taylor he had carried this process to a successful issue.

Mr. TAYLOR then exhibited some specimens, and gave an account of the manipulations requisite, stating that he always developed with protosulphate of iron.

Mr. ORANGE said that, of all dry processes, he preferred Taupenot's, especially for printing transparencies, of which he manufactured large quantities.

Mr. BURNS exhibited a number of stereoscopic prints of exquisite beauty, which were much admired. These, he said, were taken by a process which some of the previous speakers had spoken unfavourably of, but which he thought gave results which left nothing to be desired. He alluded to the process known as "Fothergill's."

A committee, consisting of Messrs. Watson, Henries, Tunny, Orange, and Dr. Paterson, was appointed to examine and report on as many of the dry processes as they judged it desirable to investigate, beginning with that of Dr. Paterson's.

Practical Instructions on Coloring Photographs.

By ALFRED H. WALL.

[In consequence of the unusual length to which our report of the meeting of the Photographic Society runs, we are obliged to postpone the continuation of this valuable paper till our next.]

The author of the preceding paper has, in order, to render his communications of greater practical value, kindly undertaken to criticise the work of, and give advice to, students, in colouring, through the medium of these pages, for which purpose specimens may be sent, with a stamped and directed envelope *for their return, to* A. H. WALL, Esq., 11, THE TERRACE, WALWORTH.

C. A. L.—A good white pigment is of the greatest importance. The best "Chinese White" I have used is that sold by Newman, of Soho Square. It is necessary to have it perfectly pure, free from the slightest taint of iron, and it should be preserved if possible from the effect of sulphureted hydrogen. I believe many water-colour drawings have been injured by hanging in a room in which gas is regularly burnt. I have tested the pigments of most makers.—With a trained eye, cultivated taste, and manipulative skill, you ought certainly to make an excellent photographer.—Body colours should never be used in water for flesh.

Foreign Correspondence.

Paris, January 10, 1860.

PERMIT me the gratification of wishing you a "happy new year," hoping that you will be even more victorious under your new ensign of the BRITISH JOURNAL OF PHOTOGRAPHY than under the old one. May the new year bring you a fresh accession of subscribers, and may they and you continue to propagate photography to the end of the present century.

Looking back upon the past year, we cannot say it was distinguished by any remarkably brilliant discoveries; let us hope that the present year will be more honoured. Our Photographic Society displays much energy and business tact, and its efforts to advance the art must be gratefully appreciated by all who follow it. MM. Davanne and Girard have reported a new stage in their researches in positive printing, and have now treated of "fixing"—certainly the most delicate and important operation in the production of positive proofs.

M. Albites, an eminent artist, and sculptor, and photographer, has invented a piece of apparatus by which he is enabled to take portraits, views, &c., in the open air, without the aid of dark box or tent. It consists in mounting the camera upon a light box, containing the bath of nitrate of silver, the bath of distilled water, and the developing bath of proto-sulphate of iron, and when pyrogallic acid is used, a sort of portfolio, one of the sides of which is formed of transparent yellow glass. There is no frame to sustain the ground glass or collodioned plate. The ground glass is applied directly against the back of the camera, and is replaced by the collodioned plate when the picture is taken. This plate, when in position, is in connection with a shutter, which follows it in every movement, up and down, or down and up; the shutter is also connected with a chain by a handle, which it is only necessary to turn one way or another to raise or lower the shutter, and to immerse the plate either in the aceto-nitrate bath, or the water bath, or in the developing bath of sulphate of iron, or in the portfolio, where it is submitted to the action of pyrogallic acid.

The collodioned plate is immersed in the nitrate bath for about ten seconds, and washed by being immersed in pure water four or five times. To perform these immersions, the plate must be taken from the focussing place, and brought again to the focus when it has been washed for the last time; the necessary exposure is given, and then the plate is immersed in the developing bath, or in the portfolio. If by any accident the image cannot be taken so promptly as wished, or there is reason to fear that the collodion has become dry, there is always this resource, by a simple movement of the handle—the collodion can be again moistened by being immersed in the bath of pure water, or even in the bath of nitrate of silver.

I hope this description will suffice to enable your ingenious readers to construct one for themselves in the absence of diagrams, which I regret being unable to send you.

Dr. Valtier exhibited a very curious photographic anomaly at the recent meeting of our Photographic Society. He had a negative of a view of Shanghai, in China, which was so altered that the strongest points had become almost invisible; the picture seemed to have entirely disappeared; yet positives taken from it were as good as others, and as full of *chiaroscuro* and detail. He asked of the chemists present an explanation of this singular fact.

MM. Davanne and Girard gave the following:—

What had disappeared from the negative was the darks, formed (according to the French theory) of metallic silver, almost pure; and these darks had become pale because the metal was transformed into the yellow sulphide of silver. Under this new form the darks are scarcely visible to the naked eye, as they have lost, if we may so express it, their visual opacity; but they have preserved their chemical opacity, so that the light passing through the negative, loses all its photogenic action. What was for the eye only a screen, and appeared a shadow of greater or lesser intensity, was a complete screen and shadow for the sensitive paper placed under the negative, and thus it was that the positive proof appeared with details which had apparently disappeared for ever.

M. Davanne proposed a new developing agent, with a view of diminishing the weight of the photographic baggage, and of dispensing with acetic acid. It consists of a mixture of gallic, pyrogallic, and citric acids, in the following proportions:—

Gallic acid	3 parts
Pyrogallic acid	1 „
Citric acid	1 „

When the proof is removed from the frame, and the operator wishes to develop it, he takes a pinch of this mixture, dissolves it in water, and employs it in the usual manner. J. P.

Exhibition.—Photographic Society, London.—The private view took place on Thursday last, 12th instant, when there was a large attendance of members and visitors. We purpose noticing the collection critically in our next.

Correspondence.

☞ We are at all times willing to assist our Correspondents to the utmost of our ability, but we can only do so through the medium of the Journal. We cannot give private replies except to personal friends.

OPERATING ROOMS.

To the Editor.

Sir,—You would much oblige by enlightening me in your next issue of The British Journal of Photography upon the following:—

In an operating room, the light of which *must* come from the south, I think there will be great difficulty and great loss of light by having to obstruct the direct rays of the sun with calico blinds. What, in your opinion, would be the loss of light by using ground glass instead of clear glass?

If the last twelve months of the Journal completes the volume, when may we expect the index? I am, yours, &c. X.

[We think that ground glass would not be advisable, because it would scarcely be sufficient to shut out superfluous light when the sun shines direct upon it, while towards the afternoon, when the sun is setting, the obstruction would be found very inconvenient. Blinds are decidedly preferable, and it is as well to have them of both white and blue calico, so that either can be used as occasion requires. When the sun shines in the middle of the day, the blue blinds are very useful, not all over the glass of course, but just to protect the sitter. It is as well to be able to arrange your sitter so as to look eastward in the afternoon, and westward in the morning. A very convenient arrangement for the blue blind is to have an iron rod along the upper part of the roof, and another just where it joins the upright; if the calico has rings at both ends, it can then be slid over any part of the floor.

We announced in our last that the index for the volume just completed would be furnished with the present number.—Ed.]

A GRAND IDEA.

To the Editor.

Sir,—I am now studying photography with a novel purpose, of which you may perhaps like to know something. The idea was suggested to me by some one who told us how we might discover if mice existed on the surface of the moon, by photographing that luminary, and magnifying the image. I tried that experiment though, and discovered—I couldn't exactly make out what, but it was *very wonderful*.

Now, I intend to photograph the apertures of key holes, and then, by magnifying them, who knows what I may not discover? Eh! Eh! Eh! Dont you chuckle and rub your hands? Isn't it a capital idea? Now acknowledge would any one but me, *Paul Pry* (I am that celebrated historical personage)—would any mind but mine have conceived so grand an idea?

Now, in return for just "dropping in" with this valuable hint, dont be offended if I find fault with the way in which you conduct your Journal.

You must know that I consider the publication of "a chiel amang you takin' *notes*" to be the *beau-ideal* of photographic journals. I get more information, of a kind that suits me, from one number of his periodical than from all yours of last year. For instance, the "chiel" makes me acquainted with all his domestic and personal affairs; you never do. He tells me about his wife, about her ideas concerning the domestic policy, and when he makes her a present, about his little boy, about his servant girl, about "his ox and his ass, and every thing that is his." I know when his pen is a bad one, what his house is like, when he goes out, when he comes in, when his friends come to see him, what they say and do, how his health is, &c., &c., &c.—in fact, all about *him*.

Now, about *you*, what do I know of you? Why, I only hear say what you are and where you live, and part of that I learnt from the "chiel" aforesaid, in his number for Dec. 15th. I dont know if you are married at all. I dont even know if you have any family, or, if you have, whether they are boys or girls, or both. Now, dont you believe that I shall continue a subscriber if I dont get more information for my money, because I shant. Again, why dont you show that you have some consciousness of your own immense importance by dropping the humble editorial "we," and substituting the "I."

I'm sure I hope I dont intrude, and am, yours, &c.

Kew Rye House, Dec. 30th, 1859. PAUL PRY, Photographer.

P.S. I am taking out a patent for key-hole photography, and will punish severely all who infringe it.—P. P., P.

ANSWERS TO CORRESPONDENTS.

☞ Numerous Correspondents, whose letters do not appear in this number, must bear with us till our next.

W. W.—Received. Report in due course.

Posed.—Line your camera with black velvet.

Emily.—Take a course of lessons in photographic colouring.

Photus.—Mr. Moule, the patentee, will answer your question.

H. N. King.—Received. Report as soon as we have time to test it.

Fides.—We shall be ready to consider any hint you may offer on the subject.

G. N——n.—English papers are preferable for positive proofs by development.

P. D.—James Seaforth.—We have an article on the subject in contemplation.

Tyro.—The process is far too difficult for you in your present state of knowledge.

Benson.—Let well alone. Why add acetic acid to your bath if it works well without it?

Alpha.—Slow development is much more manageable than quick. "Slow and sure" is a good motto.

Acton.—You need not vex yourself about so large a lens; a small one of long focus will do very well.

Infelix Puer.—You will find an excellent paper on the subject by Mr. Hardwich in the present number.

Nonplussed.—Your collodion probably contains too much water: add some made with absolute alcohol and ether.

Probus.—Chloride of barium is much more expensive than chloride of ammonium, and not any better for salting paper.

S. S.—Your albumenised-paper contains too much salt, which dissolves in the nitrate bath, and precipitates chloride of silver.

G. K. L.—Frith & Hayward (of Reigate) would no doubt undertake it. We *know* that they could accomplish what you mention in the time specified.

James R———s.—Received. We cannot find sufficient merit to accord a *favourable* notice. Had you sent your address we should have intimated this privately.

Fenwick, S.—Syrup of iodide of iron was first used in photography by Dr. Woods, of Parsonstown, Ireland, if we remember rightly, and believe that the process he used first appeared in the *Athenæum*.

Thomas Cowley.—Your note of 31st December would most probably not have been sent had you waited till the 2nd instant, as we gave in our last an account and opinion of Mr. Melhuish's metal camera.

T. Bedford.—If you read this Journal carefully you will perceive that we never under any circumstances express an opinion upon the merits of any production that we do not conscientiously entertain. We do not, however, feel called upon to express *publicly* an unfavourable opinion, unless in condemnation of what we regard as a *public injury*. See reply to James R———s above.

J. B. Williams.—Any lens supposed to be achromatised, and containing a fluid as an essential part of its construction, is faulty in principle, as variation in temperature affects the density of the fluid materially, and thus interferes with the dispersive force. The late Mr. Archer used to make lenses on this principle, but found that he was compelled to abandon them chiefly on that account.

T.—A large lens is a positive nuisance; it not only works slowly as compared with at smaller one of shorter focus, but the results are not satisfactory. Of the makers you have named No. 1 is the best; but instead of having so large an instrument for plates 8½ by 6½, you will find his No. 3 a preferable, and only a shade more than two-thirds of the price you quote for the larger one. The relative rapidityof working we judge to be thus: No. 1, say 20 seconds, No. 2, 30 seconds, or No. 3 probably 90 seconds. By adopting what we have suggested you will perhaps get the 20 seconds reduced to 15 seconds, and have a much finer image.

Caustic.—Quekett's *Practical Treatise on the Microscope* (Balliere, Regent Street), is the *best* work that we know on the subject named, but it is somewhat expensive, costing *about* a guinea We are not quite sure whether Dr. Beale did not publish something of the kind at a lower price. Dr. Carpenter's work, *The Microscope* (Churchill, New Burlington Street), contains *some* information on the subject named, and much on the use of the instrument. As we were a worker at the subject before there were any manuals to be had, we never had much occasion for them; but being personally acquainted with all the authors named we can vouch for their thorough orthodoxy.

⁂ The Title and Index for the Volume for 1859 are issued with the present Number. The complete Volume for the past year can now be had, neatly bound in cloth, price 8s. 6d. Agents and Subscribers can be supplied with loose cases for binding the last and previous Volumes.

☞ *All* Editorial *Communications*, Books for Review, *&c., should be forwarded to the Editor*, GEORGE SHADBOLT, 2, *Upper Hornsey Rise, London, N.*

All Advertisements *and* Letters *on the* Business *of this* Journal *should be addressed to the* Publisher, 32, *Castle Street, Liverpool.*

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 111, Vol. VII.—FEBRUARY 1, 1860.

It will probably be in the recollection of most of our readers that, some time back, when the Council of the Photographic Society of Scotland announced its intention of awarding prizes, under certain conditions, for the best photographs exhibited at its annual collection, and for papers read at its meetings, we expressed an opinion relative to the impolicy, and what we regarded as the injurious tendency, of the proceedings then contemplated, and offered certain suggestions relative to the method by which the advantages derived might be attained and the objectionable features avoided. Since that time we have renewed the consideration of the subject of prize-giving upon more occasions than one, and discussed it at some length. We endeavoured to show that mere successful competition was no real test of actual merit, and that the *method* of award adopted by the Scotch Society last year was faulty in principle. Whether our remarks had any effect in causing a reconsideration of the subject at the Council board or not of course we cannot tell, nor is it at all material; but it is with no little pleasure that we have to draw attention to the fact that the mode adopted upon the last occasion has been abandoned, and one in every way superior adopted for the present season.

Instead of the selection being made by collecting the votes of all the members of the Society who might choose to give one, it has now been placed solely in the hands of one individual nominated by the Council of the Society; the gentleman appointed to this rather onerous duty being Mr. Horatio Ross, one of its vice-presidents, and who is no doubt thoroughly competent to perform the task allotted to him. Had the appointment of an arbitrator even been by general vote of the members, there would we think have been no objection to the exercise of such prerogative on their part, as the uninitiated are always more discriminating in the choice of an *individual* who is to exercise his judgment in a matter of art than they are when attempting to conduct the executive function on their own behalf; but it is a matter which we think is still better done by the Council, which has in this instance exercised its authority with discretion.

It is not every one who has moral courage enough to admit having been in error even when convinced that such is really the case; but it is still more rare with a body of individuals, and consequently the more to be commended.

The present concession is quite as much as could have been expected for the current season. Indeed, after having advertised the offer of prizes under the conditions then put forth, we do not see how any further improvement in the method of carrying out the advertised undertaking could have been effected on this occasion; but with a Council animated by a spirit of progress, as we have reason to hope is the case from the evidence now before us, we shall look for still further reform next year, chiefly in an abandonment of the principle of mere competition as essential to any claim for reward, and the adoption instead, of that of conferring the prizes as marks of *recognition* of peculiar excellence or for services rendered to the art.

Thus applied, prizes may really act as a wholesome stimulus to exertion, especially amongst amateurs, with whom, by the way, most *improvements* originate, though in their application they are often, perhaps generally, distanced by their professional brethren.

We trust that the Council of the Photographic Society of Scotland will not be disheartened if it find that the awards made by its nominee do not give universal satisfaction. It is a difficult thing for a defeated candidate to be quite satisfied; but we do not hesitate to prognosticate that there will be far less of dissatisfaction than upon the last occasion.

Since writing the preceding, we have learned that the arbitrator named by the Photographic Society of Scotland has awarded one of the prizes to Mr. Henry P. Robinson, of Leamington, for his group, *Here they come!* which is also now on view at the London Exhibition (No. 429); and another to Mr. James Mudd, of Manchester, for his landscape, *Near Coniston, Lancashire*, of which a duplicate is also to be seen at the same place, and is numbered 488. We can only say that the works rewarded are in every respect worthy of such distinction, and have no doubt that Mr. Ross has faithfully discharged his somewhat onerous duty.

In Mr. Heath's description of the improvements in Smartt's tent, which may be found in the report of the meeting of the London Photographic Society, published in our last number, mention was made of a new kind of washing tray, or rather *sink*, to be used in that or any other tent, or substitute for it. Since then we have had an opportunity of more closely inspecting it, and find it even more ingenious than we at first thought it to be. The sink consists of a wooden frame-work for the sides, about three-eighths of an inch thick and an inch or inch and a-quarter in depth. The bottom is formed of sheet india-rubber attached to some textile fabric—the former serving to render it impermeable to moisture, the latter to prevent its being stretched or broken. We have called it a frame-work of wood, and so it is; for the two shorter sides of the parallelogram are attached to the longer by sliding into a small metal groove of very simple construction, while the longer sides are permanently attached to the india-rubber cloth. When in use all four of the wooden sides are external to the india-rubber tray, which is kept in form by them; but when required to be packed up, the shorter slides are slid out of their fastenings, and the longer ones allow of the tray bottom being *rolled round them* (the loose sides being first placed inside), so that when packed up the whole occupies no more space than a rod the length of the longest side of the tray, and about an inch and a-half square. At one of the corners is attached a tube to carry off the washing water, &c., and this tube is made of the india-rubber fabric; so that it is no larger when folded than a piece of broad tape, and serves when packing up the tray to wind around it, and make all "snug," as a sailor would say. The tray is really a most ingenious and convenient contrivance.

We are desirous of throwing out a friendly hint to our photographic friends in Glasgow. We understand that many are anxious to revive the activity of the Photographic Society in that city, and others who are not members to join it. We are informed also

that though this desire is unquestionable, everybody seems afraid of moving too quickly or energetically in the matter, lest he should be deemed officious. Now, this is sheer folly. Let two or three meet together and decide on some steady course of action, and the thing would be done. If any who are anxious to join in the good cause feel nervous about the matter, let them send their names to us, and when the number is sufficient to form a good working nucleus, we will advise with them, and lend them such help as is in our power.

PHOTOGRAPHIC CONTRIBUTIONS TO KNOWLEDGE.

"EGYPT AND PALESTINE:"

By Francis Frith—*Illustrated with Photographs.*

[FIRST NOTICE.]

There are but few persons in whom any mention of the localities above named does not stir up deep and lively emotions; and no wonder that it is so, for not only do the Holy Scriptures teem with direct references thereto, both in the Old and New Testaments, but they are also continually alluded to in a spiritual sense when treating of a future state of existence. One of the earliest impressions made on our childish imagination was, the flight of the Saviour into Egypt — Egypt the country in which Moses wrought such mighty wonders in execution of the awful wrath of the Almighty — where His chosen people "were oppressed four hundred years."

In the days when poetry and romance exert a potent charm over the youthful fancy, where so fitting a scene for the deeds of chivalry as Palestine, where the knights of old repaired to wrest from the heathen the holy places? This, be it remembered, is no fancy, but sober truth, albeit many tales of the wildest romance have been so mixed up and blended with the records of actual occurrences not less singular that it is no easy task to separate the two. This, so far from destroying the interest felt in a land around which the hand of the poet has cast a veil, has, without annihilating the hard lines of *fact*, superadded a softening influence that tends rather to increase the attraction.

In later life, too, when the history of the past becomes a theme so absorbing as to claim for its study the whole waking hours of many a learned man, what lands yield such a harvest of records of the past as those of which we are now treating? When recently noticing some stereoscopic illustrations of China, we could not help feeling impressed with the importance of them in an educational point of view; but, regarded in this light, what can we not say of the series of larger pictures now before us? We cannot but realise the fact that the art of photography is progressing with rapid strides, and though still but a child in years, it is doubtless destined to play an important part in the future history of civilisation. The wonder of yesterday has become the luxury of today, and will most surely arrive at the stage of being the *necessity* of tomorrow. It will no more be possible to do without photography than without the printing press — to annihilate which would be to cut off half our existence.

We have noticed of late a growing increase in the importance of the works dependent upon photography for their being; but of all that have hitherto been issued none have approached in grandeur of scale and excellence to the two truly magnificent volumes now before us, published by Mr. James S. Virtue, of the City Road, and of Ivy Lane, London.

These volumes — got up in a style that renders them a fit ornament for any drawing-room — contains no less than seventy-five views, chiefly of the highest order of merit as regards execution and interest of subject, and are such as are calculated to make the work an addition of importance to any library. In them the artist, the antiquary, the architect, and the historian will find abundant material wherewith to satisfy the cravings of their respective desires, while the general admirer of the beautiful will be no less gratified.

The very titles of the illustrations are enough to arrest the attention; and when we say that in general the execution of each picture is worthy of its subject, we can scarcely pronounce much higher commendation. Were we to assert that in all the proofs the execution is equal we should be misleading our readers; when could such a declaration be truthfully made with regard even to any extensive series of engravings? How could it then be expected that in photographs perfect uniformity could be attained? None of the series are mediocre—all have considerable merit—whilst by far the majority are of a *very* high character; those that are the least satisfactorily treated being the extended distant views, such as Bethlehem, Distant View of Damascus, and one or two others, in which a want of definition rather mars the effect. It is possible that the defect named may have arisen from an imperfection in the lens employed, or for the want of a little humouring, which some lenses require when taking "distance." With these trifling exceptions, we have scarcely a fault to find with the entire series.

This magnificent work is issued to subscribers only, and is completed in twenty-five parts, each part containing three views, of about nine inches by seven inches in size, accompanied by descriptive letterpress, on which we have somewhat also to remark.

In most works of illustration the letterpress is commonly treated as so much waste paper. It is, however, not likely to meet this fate in the work before us, it being interestingly descriptive, lively, and to the purpose, without being too diffuse, as is commonly the case. It is written by Mr. Frith, and though much consists of compilation, much also is original. Where extracts have been taken from previous publications they have been judiciously selected, and only resorted to when the information given is such as could not have been so readily acquired by the author's own experience.

We consider, by the way, that we have a right to regard Mr. Frith with peculiar interest, he having been originally a Liverpool Photographer.

Besides the mass of information connected specially with the various subjects delineated, there is much also of interest to the *photographer*, and the whole is put together in a very pleasant, unconventional style. There are many little extracts that we should like to have given, but our space will not permit us to indulge in more than the two following — for the present at least. We will begin with something photographic: let us take the introduction:—

"Salaam! — Peace be with thee, oh, thou pleasant Buyer of my book!

* * * * * * * * * * * * * *

"It is my intention, should my life be spared, and should the present undertaking prove successful, to present to the public, from time to time, my impressions of foreign lands, illustrated by photographic views.

"I have chosen, as a beginning of my labours, the two most interesting lands of the globe — Egypt and Palestine. Were but the character of the pen for severe truthfulness as unimpeachable as that of the camera, what graphic pictures might they together paint! But we scarcely expect from a traveller 'the truth, the whole truth, and nothing but the truth.' Hear Albert Smith, himself an accomplished traveller, and a popular author:— 'Artists and writers will study effect, rather than graphic truth. The florid description of some modern book of travel is as different from the actual impressions of ninety-nine people out of a hundred, allowing all these persons to possess average education, perception, and intellect, when painting in their minds the same subject, as the artfully tinted lithograph, or picturesque engraving of the portfolio, or annual, is from the faithful photograph.' Nobody that has ever floated in a *dahibieh*, will argue that any existing Nile book conveys 'graphic truth.' Yet it does not follow, O Albert Smith, that a photograph, because it is not 'over-coloured,' is therefore *faithful*. I am all too deeply enamoured of the gorgeous, sunny East, to feign that my insipid, colourless pictures are by any means *just* to her spiritual charms. But, indeed, I hold it to be impossible, by any means, fully and truthfully to inform the mind of scenes which are wholly foreign to the eye. There is no effectual substitute for actual travel; but it is my ambition to provide for those to whom circumstances forbid that luxury *faithful* representations of the scenes I have witnessed, and I shall endeavour to make the simple truthfulness of the camera a guide for my pen.

"Now we shall see (if my bungling does not spoil the match) what sort of chance Fact has with Fiction in the race for popularity.

"It is certain that a very large proportion — probably two-thirds — of the entire reading of the British public consists of works of fiction. Everybody, almost —

> "In these o'erpolish'd times,
> Can shed the tear o'er woeful rhymes;
> O'er plot of novel sore repine,
> And cry for hapless heroine!"—*Hogg*.

But few, I fear, can tolerate simple truthfulness: there is not enough of excitement in it. Even Englishmen relish a little of that pleasant hyperbole which the Orientals stretch to its limit of tension. It is remarkable that perhaps every book of world-wide fame (except the Holy Scriptures) is a romance. Shakspeare, Milton, Dante, nearly all the poets are novelists. Cervantes, Bunyan, De Foe, Harriett Stowe — all novelists. Furthermore, a man sitting quietly at home in London or New York may write even a Book of Travel, and an artist may compose for it a series of illustrations, with every chance of success, upon the most scanty materials, and without the cost and labour of travelling. It is an artist's privilege to 'make a picture' of his subject; but, alas for the poor photographer! and alack for the man who will write the truth, if he can, at all hazards!—they must be dull.

"A photographer only knows — he only can appreciate the difficulty of getting a view satisfactorily into the camera: foregrounds are especially perverse; distance too near or too far; the falling away of the ground; the intervention of some brick-wall or other commonplace object, which an artist would simply *omit*; some or all of these things (with plenty others of a similar character) are the rule, not the exception. I have often thought, when manœuvring about for a position for my camera, of the exclamation of the great mechanist of antiquity — 'Give me a fulcrum for my lever, and I will move the world.' Oh, what pictures we would make if we could command our points of view!

"I may be allowed to state, as giving additional value to good photographs of eastern antiquities, that a change is rapidly passing over many of the most interesting. In addition to the corroding tooth of time, and the ceaseless drifting of the remorseless sand, temples and tombs are exposed to continued plundering: governors of districts take the huge blocks of stones, and the villagers walk off with the available bricks, whilst travellers of all nations break up and carry off, without scruple, the most interesting of the sculptured friezes and the most beautiful of the architectural ornaments.

"The difficulties which I had to overcome in working collodion in those hot and dry climates, were also very serious. When, at the second cataract, one thousand miles from the mouth of the Nile, with the thermometer at a hundred and ten degrees in my tent, the collodion actually boiled when poured upon the glass plate, I almost despaired of success. By degrees, however, I overcame this and other difficulties; but I suffered a good deal throughout the journey from the severe labour rendered necessary by the rapidity with which every stage of the process must be conducted in climates such as these, and from excessive perspiration, consequent upon the suffocating heat of a small tent, from which every ray of light, and consequently every breath of air, was necessarily excluded.

"I think I will confess to a weakness for rapid production in all that I undertake. My views have been taken, for the most part, whilst my friends were hastily inspecting the scene or object copied; and, as for my letterpress, I can only write rapidly, and in the very words which first occur; I dare not revise — out goes one-half that I have written, and the remainder is intolerably dull. I have, however, one consolation, viz., that if the critics will be good enough not to call disagreeable attention to my writing, not one person in ten will think of looking at it. Scarcely any one ever *does* read the letterpress which accompanies a series of views, any more than one thinks of scrutinising the 'gold sticks' who shuffle, as a matter of course, after a royal pageant. Doubtless I am indebted for this security to the learned dulness of the great men who have hitherto invariably written for illustrated works, not one of whom, as far as I recollect, has been personally acquainted with the scenes which he undertook to describe. I am perfectly content that my own descriptive matter should be thus considered as entirely subordinate to the views. I have neither had time for elaborate investigations on the spot, nor is present space afforded for much topographical or critical detail: upon such points I shall often prefer simply to quote the opinions at which other and more useful investigators have arrived."

In order to give his subscribers an idea of the costume of the true believers, as the followers of Mahomet style themselves, Mr. Frith presents his own portrait as he appeared when attired as a Turk, touching which he says:—

"Turkish trowsers I shrink from describing; but if any of my readers have a fancy for a pair, they are welcome to the following recipe, which I pledge myself is literally correct:—Take four yards of broad-cloth of some brilliant colour, fold the piece in the middle and sew up the end; you will thus have a bag six feet wide and five feet deep, open at top and at bottom; sew up the bottom, except a small hole at each extreme corner for the feet to come through, and your trousers, *à la Turque*, are complete. To wear them the top of the bag must be bodkined, puckered, and gathered round the body with a worsted sash of bright colours and voluminous folds. The two yards of heavy double cloth which, as it were, webs the legs together, like the connecting membrane of the foot of a goose, hangs, you may imagine, with awful square solidity in the mid space; and when the fat gentleman walks, or rather waddles and rolls along, how it sways, and pendulates, and thumps, first against one leg and then against the other!"

There is one little matter for which we feel some regret, and that is, that in consequence of the publication being in "parts," the proprietor has judiciously enough managed to issue in each of the "parts" as great a variety of subjects as possible; but the binder of the book has *as injudiciously* arranged them in precisely the same order (a proceeding wholly unnecessary, as neither the plates nor the letterpress bear any paging or numbering), and we are consequently bandied about from pillar to post—now Egypt, now Palestine—up and down, backwards and forwards, in the most erratic manner possible. We would strongly recommend the numerous subscribers whom we are convinced will become purchasers of this beautiful work to have the several plates with the descriptive letterpress arranged in something like an order of locality for binding, which could very readily be done with but little trouble.

In our next we shall proceed to describe critically the magnificent plates which illustrate the work.

ON THE OPTICAL CENTRE.

By Thomas Grubb, M.R.I.A.

No. I.

In proceeding to treat of the *Optical Centre* (real or imaginary) *of a combination of lenses having one or more intervals between*— such for example as the photographic portrait combination — it seems desirable to commence by ascertaining precisely what is meant by the term when so applied.

I apprehend that no definition of such a centre is extant, and that we shall not find (probably with reason) such a centre treated of in any optical work. To photographic publications, then, we are referred for a knowledge of what is meant by the term; and here we find that when the question of the best place for the limiting diaphragm (or stop) in a portrait combination is discussed, some will advocate placing this diaphragm between the first and second combinations, where the optical centre is situate; and in that combination described as the symmetric triplet, the optical centre is assumed to lie in the centre of the combination, and from which position of the optical centre certain good qualities (real or unreal) are inferred.

We therefore are not left at any loss to conclude that what is generally understood of this optical centre is, that such compounds as I have alluded to have each a fixed and determinate centre, *analagous to the optical centre of a single lens*,— one not variable, or to be disturbed by the circumstances under which the compound is used, but remaining *intact* so long as the compound remains unaltered. We may in vain look for such an optical centre. The idea is evidently borrowed from the circumstance that every individual lens has its fixed and determinate optical centre, which centre, as it is treated of in all elementary works on optics, I think it unnecessary to enlarge on here; but for the information of those who wish to avoid the trouble of reference, I may state that in an equiconvex or concave lens this centre will be found in the centre of the lens. In the plano-convex or plano-concave it touches the curved side, and in lenses which have one surface convex and the other concave, the optical centre is outside the lens, and on that side which has the greater curvature, in all cases this centre being found somewhere *in the axis of the lens*.

I am not aware of any standard work on optics being published since the portrait lens has assumed an importance demanding a theoretical investigation of its principles. All that was previously required in that way was nearly comprehended under the aplanatic telescope, where the intervals occurring between the lenses of the object-glass are so small as may well be neglected. The portrait lens, as also analagous combinations, present a widely different case. No adequate idea of their principles of working can be arrived at without making due allowance for the intervals between their respective lenses; and the most we shall find for our guidance here in standard works on optics is, perhaps, some general analytical expressions of the theory of such compounds, with an announcement either that the investigation is complex or difficult.

By pursuing the method of diagrammetrical illustration, I hope to be able to lay within the reach of those who are desirous of investigating the subject more fully, sufficient for this purpose, at least for a commencement. I would also hope to show the mere

cursory reader (whom I shall also suppose to be an experimental photographer) that the examination of the merits or qualities, individual or comparative, of such compounds is by no means that light or easy matter which is commonly considered.

I shall commence by asking the reader to get rid of all idea (should he entertain such) of a *fixed* centre appertaining to any *open* compound (by which term I propose to express such as have one or more intervals between the lenses). True, the change of place of any centre we may be able to find in such is not great in amount, as we shall see hereafter; but its amount is quite adequate to destroy all idea of fixity, as well as to place in the category of "for further examination" any theory which may depend for its own correctness upon this assumed fixity.

(To be continued.)

FAILURES IN THE WET PROCESS: THEIR CAUSE AND CURE.

By Mr. Leake, Jun.

[Read at the South London Photographic Society, January 19, 1860.]

A short time since we were favoured by our vice-president with a valuable and interesting paper on failures in the dry collodion processes. This evening, by your permission, I purpose offering a few hints on some of the failures most commonly met with in the wet collodion processes; and, lest I should be accused of wishing to teach my grandmother, &c., permit me to state that I have not written this paper so much in the hope of imparting information to others myself, as in the hope of eliciting it in discussion from those gentlemen present who are so well qualified to teach.

Notwithstanding the difficulties — and they are not few — at present wet collodion is unrivalled for sensitiveness, certainty, and, I think, beauty of result; and I consider the extra trouble of more apparatus is compensated for by your ability to determine on the spot the success or failure of the operation, while the extreme sensitiveness of the surface enables the operator to produce perfect pictures of objects in rapid motion — a feat yet *to be* performed by the dry process. I will not further trespass on your time by speaking in favour of a process adopted as the best by such photographers as Fenton, Rejlander, and Lake Price, but will proceed at once to point out the causes of the failures which most commonly occur in its practice.

Failures in the wet collodion process may be classified as follows: — First, those arising from external conditions, as intense heat, or extreme cold, &c.; secondly, those from defects in the chemistry of the process; and, thirdly, from defective manipulation. We will, if you please, consider these in the order I have just given, and I will endeavour to lay before you a specimen of failure from each of the causes I shall mention, hoping that, in each case, the recognition of our enemy may lead to its expulsion from our future operations. I suppose all who have worked this process through a hot summer have met with failures from intense heats. The most common effect is that exhibited in plate No. 1, viz., a general muddiness, weakness, and tendency to fogging, from the film becoming dry. Of course this takes place more rapidly in hot than in cool weather, consequently exposure and development should follow the excitation at as short an interval as possible.

But by far the most common failure from intense heat is the deposition of silver on the shadows of the negative during development, as in plate No. 2. If the development be finished when this action is set up the high lights are entirely dissolved, and instead of a negative, we have a positive by transmitted light.

During the intense heat of last summer (the temperature ranging from 90 to 110 degrees), I was much annoyed by the occurrence of this failure, the second application of the developer invariably spoiling the picture. The process of development was that with sulphate of iron and subsequent intensifying with pyrogallic acid. I found there were two remedies for this evil: the first was fixing after the first development, and then intensifying with pyro' as usual; and the second, pouring a solution of tincture of iodine over the plate after the first development, then giving a short exposure to light, and intensifying with pyro' and silver as before. The tendency to solarisation, always so manifest in hot weather, may often be almost entirely obviated by the use of a small stop.

From the fact that our most intense heat and powerful light come together, I am inclined to think that our pictures are more often solarised from over-exposure than we, not knowing the power of the light, imagine.

In briefly noticing failures from extreme cold, the converse of the remark just made will apply; and I certainly think that the cold is often set down as the cause of failure when the light is so deficient in actinic power that no amount of exposure will produce a brilliant picture. When this is the case the lights of the picture will be solarised, while the shadows will be scarcely impressed. The picture I exhibit as a specimen of failure from this cause was exposed on a warm October afternoon, clearly proving that cold was not in this instance the retarding agent.

Again, even in our operating rooms, where the temperature is artificially kept up, we often fail; and I think no one would, as a rule, like to compare the negatives taken in November with those produced on the brilliant days of May or June. However, that cold retards the development there can be no doubt; consequently, keep the developing solutions in a warm place, and if the temperature be very low, increase the amount of the reducing agent, without adding to the retarding agents—as acetic or citric acids. I do not think much is gained by warming the bath, and in some cases I consider it an evil. In out-door work, for example, if you take a plate from a warm bath into the cold atmosphere, you condense the moisture which is evaporated from the plate upon the lenses, and, of course, fogging is the result. In any case, I cannot see that anything is gained, more than a little time in forming the coating of iodide; and the old proverb, "Keep your feet warm and your head cool," as applied to photography, would be, "keep your developer warm and your bath cool," to which I will venture to add, by way of finishing this part of the subject—and your tempers also; for if your experiments are continued through November in London, depend upon it they will be severely tried.

We now notice some of the failures arising from defect in the chemistry of the process. Those we shall refer to at this time are:—*Alkalinity of the nitrate bath, acidity of the same, contamination by organic matter, weakness and excess of strength, and some also of the defects most commonly met with in the collodion and the developer.* Alkalinity may arise from various causes, such as using an alkaline collodion, or adding a solution of very highly-fused and alkaline nitrate of silver; but it will more often occur from an excess of alkali having been added in the attempt to correct acidity. Of all failures from a defective bath this is the easiest both of detection and cure. No one having seen a failure from this cause, will ever confound it with failure from others. (See plate 4.) Of course the remedy for this is to add acid in sufficient quantity to neutralise the bath. If for producing positive pictures, nitric acid may be used, but for negatives acetic acid will be found the best, as it to some extent favours density of the image. It is mostly recommended that the negative bath be kept perfectly neutral; and, if extreme rapidity be desired, this *must* be done; but for general purposes, both in landscape and portraiture, a trace of free acid in the bath will be found to give the best results.

Acidity of the bath next claims our attention. As before stated, a trace of acid in the bath will not be injurious; but, if an excess be allowed, a great loss of sensitiveness will result, the deepest shadows will be deficient in half-tone, and, if there be a *large* excess, the half-tints will be altogether lost.

In mixing a new bath, if a pure, neutral, nitrate of silver be used, one minim of glacial acetic acid to sixty ounces of bath solution will be found sufficient to preserve clearness and brilliancy. Plate No. 5 will give some idea of the effect of an excess of acid in this part of the process. If a very large quantity of acid be present, especially *nitric*, fogging may take place; but this will not often occur, unless it has been purposely added. To neutralise the free acid, either ammonia or carbonate of soda may be used, care being taken not to add an excess, especially of the former.

When a bath has been in use for a long time, it often becomes contaminated by organic matter, and almost saturated with ether. When in this condition, muddy lines will often be formed by the running down of the solution after leaving the bath. The best remedy for this, if the bath be not very strongly contaminated by organic matter, will be to take out, say half the old solution, and replace it by the same quantity of nitrate of silver solution, without the addition of iodide or acid. If, however, much foreign matter be present, it will be cheaper and safer to set the bath aside for other purposes, and begin afresh with a new one. A bath will often become acid by use, more especially if a collodion containing free iodine be used; this, in combination with the ether and other matters just noticed, often makes an old bath work so unsatisfactorily that it is generally better to reject it at once, and precipitate the silver for other purposes.

A bath used for exciting collodion should be used for no other purpose, and the fewer alterations and additions made in and to it, when once in working order, the better. It has been recommended that the plate should be coated with albumen before collodionising. I think this would spoil the bath as soon as anything, by making it

work more slowly, and eventually fogging to such an extent as to be perfectly useless. When a bath becomes contaminated by this, or by any other organic substance, a good shake up with a little kaolin will be found safer and better than rinsing or any other method of removing it. A bath which has worked so badly as to be quite useless, may often, by this means, be restored and made workable in a couple of hours.

With regard to the next point—the strength of the bath—I am aware there is a diversity of opinion, some recommending a strong bath, and others a very weak one. I prefer the first under most conditions, and generally keep it at from thirty-five to forty grains for portraits, in-doors, and from thirty to thirty-five for out-door work, though, if the temperature be very high, it may be advantageous to lower them five or ten grains. If a negative bath be allowed to fall below the strength just given, the pictures will be (with most varieties of collodion) deficient in half-tint and intensity (see plate No. 6), and no amount of care in exposure, &c., will enable the operator to produce a brilliant result. If, on the other hand, the strength of the bath be too great, the pictures will most probably be slightly foggy, and sometimes streaky, especially if allowed to remain long in a newly-mixed bath.

I think, in respect to failures from a defective bath, that a little *tact* is often better than a great deal of chemistry. Keeping the plate in motion will often remove streakiness, and early removal from the bath prevent fogging; and when this is the case, I think it unwise to tamper with the bath, more especially as it will often come round if left to itself.

The failures we shall next notice are those which may occur from bad collodion, or the improper use of good. It may be as well to state that I have usually procured my collodion ready made, and have, consequently, had no experience in its manufacture; therefore the defects I shall notice will be those most commonly met with in the commercial varieties, and of these I shall not attempt to suggest the cause, but simply confine myself to offering a few hints on their removal.

The defects most commonly met with are—*excessive intensity without half-tone; excess of half-tone without intensity; splitting up of the film on drying; glutinosity and over-iodising.* For the first mentioned I think sulphate of iron in development will be found generally the easiest and best remedy, if the collodion must be used by itself; but if any of that which is defective from excess of half-tone is at hand, it is advisable to try that of mixing them in various proportions: this will often be found successful, though not invariably. The restraining acid in the developer may also be diminished in quantity, and if these expedients, in combination with a full amount of exposure, do not give the required softness, it may, I think, be safely inferred that the sample of collodion is almost useless. Bromine has been recommended as diminishing the intensity and increasing the amount of half-tone, but as I have not tried this I can give no opinion.

The defect we next notice—half-tones without intensity—is, I think, much more rarely met with, and more easily remedied than the first. I would advise, when a collodion of this description is met with, that the effect of mixing with the first-named variety be tried, as before suggested. If this is unsuccessful, increase the quantity of acid in the developer; use pyrogallic in preference to sulphate of iron, for this purpose, and give a very short exposure.

I think that in this case, also, if these precautions fail to produce the desired effect, the collodion may be safely set aside as at least not first-rate.

Splitting up of the film in drying is the next defect we have to notice. It is not often, comparatively, that we meet with a collodion defective on this point. I think the best remedy will be found in adding a small quantity of alcohol, and allowing the film a long time to set before immersion in the bath. Care should also be taken to have the plates perfectly clean and dry before coating with collodion.

The use of a collodion too newly iodised is a very frequent cause of fogging, especially in out-door photography. (See plate No. 7.) Of course I need not point out the remedy here, but will merely remark that I prefer iodising about twenty hours before use.

Failures from old and partially decomposed collodion are more rare, as the liberation of free iodine generally warns us that decomposition has set in. In some cases, however, the characteristic colouration does not take place. A collodion iodised with cadmium will often become almost useless from decomposition (as I think) of the pyroxyline without changing colour to any great extent. In this case the only method of determining its age will be by its behaviour during development: if, after a full exposure (the bath, &c., being in proper order) it presents the appearance of plate No. 8, viz., great intensity in the high lights, the detail in the less illuminated parts being very faint, it may be safely set aside as useless, for the wet process at any rate; and none of the processes recommended for the restoration of sensitiveness have in my hands proved of any practical utility.

A glutinous collodion is not frequently met with in practice. I think it will mostly be found to occur in samples iodised with cadmium. In some cases the amount of glutinosity is so small as not to cause great inconvenience in coating plates of moderate size; while at others it will be present to such an extent as to preclude the possibility of obtaining an even film. I think the addition of alcohol will be found the best and readiest method of mitigating this evil. I say mitigating, because I doubt if it can be altogether removed, as it no doubt arises principally from the defective pyroxyline used in the plain collodion. The operation of coating should be performed as rapidly as possible, a large quantity of collodion being poured on and off quickly. At times thickening of the film will occur with a collodion which is not glutinous, especially in warm weather. For this defect, also, the addition of pure alcohol and perhaps a small quantity of ether will generally be found the best remedy.

The last defect we shall notice is that from over-iodising the collodion. I think this is a very frequent and prolific source of those small transparent spots which are so often seen in collodion negatives. (See plate No. 9.) The best way of removing these troublesome visitors is to add plain collodion till the defect is remedied.

In concluding these hasty and imperfect remarks on collodion, I would observe that operators generally do not take into consideration the fact, that a peculiarity which may at first sight seem a defect, may often, when skilfully applied, be made a positive advantage; and that any collodion, however good, may be made to produce, and indeed must produce, indifferent pictures if not properly applied. Of this I have seen many instances. An operator having a room lighted so as to give great intensity of light and shade will condemn a collodion similar to the first I have mentioned as totally unworkable, but will uphold the second as the best which can possibly be made; while another working with a very diffused light, giving a great amount of half-tint, will of course take the directly opposite opinion, and thus much difference exists betwixt tweedledum and tweedledee, both being right and both wrong, and the unfortunate manufacturers of the collodion are blamed because their preparations are not properly used or applied.

I do not think there is a collodion made which will render any and all subjects to perfection: one variety will answer best for portraiture, another for landscape. And when thus classified, other sub-divisions may often be made: one variety will perhaps render foliage beautifully, but totally fail if applied to architectural subjects; another will give fine results in foreground, but fail dismally if distance be required. I would, therefore, recommend all who work out of doors to provide themselves with several sorts of collodion; and I think that by so doing they will often secure a better result than if the precaution of adapting the collodion to the subject to be photographed be neglected.

May I suggest to those gentlemen who practice the dry processes the palpable advantage of preparing their dry plates with collodion of various kinds instead of as at present, each operator using one sort only for all purposes?

In the development perhaps the only matter of import is to use the developing agent quite fresh. A moment's consideration of the chemistry of this part of the process will convince on this point, and all the defects which theory would indicate as likely to occur will certainly be met with in practice. The iron developers are especially liable to decomposition and should therefore be used immediately after mixing.

I wish to call the attention of those gentlemen who practice the dry processes to the fact that Fothergill plates may be developed with the iron solutions. Mr. Leake, Sen., has developed some plates after exposure to gaslight under a negative, one of which I produce for your inspection. The process appears to me quite successful. I think that if dry plates can be developed in this way it may be advantageous—first, as giving a softer picture and shortening the time of exposure; and secondly, that it may, to some extent, obviate that frosty appearance so often met with. The plate before you is developed by iron alone, but I think that for negatives a subsequent intensifying with pyrogallic acid will be required.

I feel some hesitation in introducing the few remarks I have now to make on failures from defective manipulation on account of their very elementary character. I will not, however, detain you long on this subject. The first manipulatory failure I shall notice

is that from dirty plates. I suppose we all know, by painful experience, the effects thus produced. Perhaps soap marks are the most difficult of removal. We all know how interesting it is to see a huge figure eight looming through a negative during development, especially as the negative in question is sure to be in all other respects perfect. I produce a specimen of marking from that cause. Some glasses are more difficult to clean than others, and some will, I think, defy your most energetic efforts. Perhaps the best solution for cleaning plates is that recommended by Mr. G. W. Simpson, in a recent number of the Journal. I think that more failures occur from damp than dirty glasses, and would advise that the plates be always gently warmed before coating if the atmosphere be at all damp.

Imperfections in coating will sometimes occur. These are more frequent in hot weather, and generally consist of thickenings of the film at the end of the plate at which the collodion is poured off. (See plate No. 12.) This often arises from the evaporation of the ether during the coating of large plates in a warm room, and the best remedy is dilution with alcohol and ether, and coating the plates as quickly as possible.

By placing the defective end of the plate in the slide so as to receive the impression of the sky, when taking views, or the feet of the sitter in portraiture, this defect will often be lost sight of.

I think that as a rule there is not enough time given between coating and immersion in the bath. I like the collodion to have set enough to bear the impression of the finger on the lower edge, and I think few failures occur from allowing too long a time in this part of the process, except the temperature be very high.

If the plate be removed from the bath too soon, greasy marks will occur from the solution running in lines upon the plate (see plate No. 14); but if, on the other hand, it be allowed to remain too long in the solution most likely fogging will result. Some persons recommend a long immersion; I cannot see that any thing is gained by keeping the plate in the bath after the film of iodide is formed, but have often found it a positive disadvantage in hot weather or when working in a tent. I think it a great mistake to use a bath which contains so small a quantity of solution. I prefer one in which a large number of plates can be coated without necessitating any addition of fresh solution, and which is sufficiently large to allow the plates to be immersed without cornering, as any hesitation in this operation produces a line similar to those on plate 13. Upon removal from the bath the plate should be well drained, and the back and top edge dried with blotting paper in order that the solution may not run down, as this would produce muddy lines. (See plate 15.) I think it a good plan to lay a sheet of blotting paper quite over the back of the plate when placed in the slide: this keeps the slide dry and clean. It is a common mistake to suppose the plate must be exposed directly it leaves the bath; if the weather is cool and the plate be carefully drained, fifteen or twenty minutes may be allowed to elapse between exciting and developing, though, of course, these operations should follow each other at as short an interval as convenient.

On leaving the dark room the slide should be covered with a cloth, as a precaution against stray light, and this should not be removed until the plate be safely deposited in the dark room after exposure. The fault most often met with in collodion negatives is under-exposure. An insufficient exposure necessitates a long development, and this produces that snowy appearance we so often see in foliage, especially if the development be pushed with nitrate of silver. I like, if possible, to expose, so that one application of the developer is sufficient to bring out the detail in deepest shadow. Of course if an insufficient exposure be given, the detail in the shadows will not be rendered (as is the case in plate 16); while if it be excessively prolonged, the lights and shadows will appear at once, on the application of the developer, and there will not be sufficient contrast between the lights and shades in the finished picture. (See plate No. 17.)

It is always advisable to shield the lens from the direct rays of the sun, by placing a funnel or by holding a piece of cardboard over it. I do not like too small a stop, as I think the smaller the stop the more flat will be the picture; of course within certain limits.

In developing failure may arise from several causes. I think over-development is of these the most frequent, and excessive intensity is the result. (See plate No. 18.) Under-development, on the other hand, gives an insufficient amount of intensity, and the picture is red, weak, and more or less defective in the shadows. (See plate No. 19.) Of course the remedy for these failures is obvious. In pouring on the developer care should be taken to let it cover the plate at one sweep, as the least hesitation will produce a stain; and also to have sufficient alcohol to make it flow easily. If developing views I prefer pouring the solution on at one corner of the sky, as a slight loss of intensity at this part of the picture is of no importance, and in portraiture I prefer developing from the feet of the sitter.

Much depends on judicious development, and a great deal of effect may often be produced by pouring the developer on, or keeping it off one part of the picture, as more light or shade be desired.

The only precautions to be observed in fixing are, to be careful the solution of cyanide is not to strong, and that if hyposulphite of soda be used, that it is thoroughly removed by the subsequent washing.

I exhibit a specimen of the injurious effect of leaving any of the fixing agent on the plate. (See plate No. 22.) I think a weak solution of cyanide is preferable to hypo', as it is quicker in its action and more easily removed by washing.

I have now, last of all, to call your attention to some varnishes at present in the market, which, if not carefully used, dissolve the picture entirely out. I believe the remedy here is warming the plate before applying the varnish, but I think it would certainly be safer to reject it at once. I produce a specimen of the effect produced by this varnish, (See plate No. 23.)

I have now, gentlemen, only to thank you for the kind attention you have paid to a paper which I fear is "flat, stale, and unprofitable" to most of you, and to hope that a bad paper may lead to a *good* discussion.

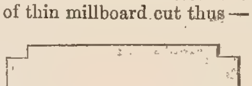
PHOTOGRAPHERS THEIR OWN ARTIFICERS.

By Thomas Gulliver.

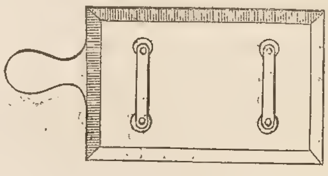
No. III.

DEVELOPING TRAY PLATE BOXES, &c.

To complete the fittings of the tent described in No. 104, we require two plate boxes, made specially for wet plates, and a developing tray. The grooves for the plate boxes should be of the V shape, which are easily made thus:—Buy a three-eight inch rabbet plane, and make a gauge line down the centre; then plane away each side to the required angle, and grind the plane-iron to fit; and having selected a straight-grained piece of wood, divide it with the compasses into regular divisions, and sprig a straight-edge on to the piece at the first division. It will be desirable to screw a strip of hard wood on to the side of the plane to secure an equal depth of groove. Having worked out the first groove, shift the straight-edge on to the second division, and so on till the required number are complete. The two ends of the plate box should be worked out of ⅜-inch stuff, and should be 8¼ inches long by 1⅝ wide. The sides should be of a ¼-inch, 8⅜ inches long by 7⅝ wide. A box of these dimensions will contain six plates 8½ inches by 6½. Two of these boxes will be wanted for the tent — one for clean plates and the other for the negatives when taken. The boxes should be well varnished, and made smooth inside to allow of their being washed out after use, as the syrup used to keep the plates moist is apt to collect dust. The boxes should be fitted with lids, which may be easily made out of thin millboard cut thus —



the sides to be turned up and paper pasted over all. When dry, varnished. An elastic band passed over the box and nailed up at the bottom of it will keep the box lid in place, and will be found more convenient in practice than boxes with hinges. The deve-



loping tray should be 9½ inches by 7½ outside measure, the ends ½-inch, and the sides and bottom of ⅜-inch wood. The handle must be placed a little to the left of the centre. Two small strips screwed on to the bottom serve the double purpose of making it stronger and to hold the plate while it is being developed; and, as additional security, two round pieces of vulcanised india rubber are fixed on to each strip. The tray inside need not be more than

three-quarters of an inch deep, and the strips half an inch. The sides should be bevelled off towards the centre, and the whole tray well varnished.

The rest of the fittings will be a small case, to contain two two-ounce bottles of collodion, and two four-ounce ones of developer, a small bag for a wet sponge made of waterproof material, and a plate-holder.

The camera is made portable and contrived to go inside the tent, and in weight is very much lighter than those in general use. I will send a description of it in my next.

The whole of the apparatus is intended for plates 8½ inches by 6½, as that size will be found most convenient for ease of manipulation and printing, as the sheets of printing paper cut into six each without waste.

I enclose a print of Oystermouth Church on plain paper, in which you will see the genuine effect of light given in the sky and over the building by using the proto-sulphate of iron developer.

[The photograph received is sharp and clear, well printed, and nicely toned—but a trifle *too cold*. We prefer the sky to be a *little* brighter, not white, but scarcely so leaden in hue.—ED.]

ON FIXING POSITIVE PROOFS.

By MM. DAVANNE and GIRARD.

(*Continued from page* 22.)

ON THE ACTION OF VARIOUS FIXING AGENTS ON THE PROOFS.

THE agents employed for fixing positive proofs are the most energetic solvents of the salts of silver — hyposulphite of soda, cyanide of potassium, and solution of ammonia. The solvent properties of the cyanide, however, are so energetic, that it is dangerous to employ it. To make use of these fixing agents, they are dissolved in water in varying proportions, and the proofs immersed in the solution when taken out of the printing frames. It is a good plan to wash the proofs in clean water before putting them into the fixing solutions, to remove the free nitrate of silver, and allowing only the chloride to remain. Water, although, strictly speaking, not a fixing agent, still performs an important part in the operation of fixing; and, in the first place, we must inquire if this liquid fulfils the aim proposed — that of dissolving all the free nitrate of silver. Now, when we immerse a sheet of paper in a solution of nitrate of silver, and without exposing it to light, we attempt by a washing in distilled water to remove all the argentine salt it retains, we perceive that the solution, although considerable, yet is not complete. The sheet of paper, however long we may prolong the washing, takes, under the action of light, an uniform grey tint, indicating a reduction of silver. Doubtless a portion of the nitrate of silver is decomposed by the salts always contained in the papers, and forms in the pulp of the paper insoluble argentine compounds, which the light afterwards attacks. Besides, the quantity of salt of silver remaining, and consequently the reduction, are both very feeble, so that in the ordinary processes of photography, where the true fixing agent must intervene after the water, this method, from the advantages to be shown in the sequel, must be strongly recommended. But water, if employed alone, is but an inefficient fixing agent, even when the paper has been prepared with soluble salts only.

This fact established, we will next examine the manner in which each of the three fixing agents proposed, under three different points of view, as enumerated in the previous chapter.

1st. The first question that presents itself is — Does the fixing agent remove all the compounds upon which the light has acted?

To verify this fact, after preparing some sensitised paper in the usual manner, it is allowed to dry, then passed through the several fixing agents; and then examined to see if, on the one hand, the papers thus fixed are still sensitive to light, and on the other, if analysis can detect the presence of silver. By proceeding in this manner, we recognise that cyanide of potassium, in the proportion of two parts to one hundred of water, left no insoluble compound; that hyposulphite of soda and ammonia acted in the same manner upon ordinary sized papers, but that the fixing agents left upon the albumenised papers a small quantity of silver susceptible of becoming slightly coloured under the influence of light.

These results are of some importance; if the first were but little known, it was not the case with the last. They show that it is difficult to remove the last traces of the silver salt from an albumenised proof, and consequently explain the difficulty photographers experience in obtaining pure whites upon albumenised paper.

2nd. We now arrive at the most difficult and important question in the subject. It may be stated in the following terms: — Does the fixing agent leave in the proof any substance susceptible of producing an alteration, either immediate or remote? Ammonia, employed in solutions of different strength, always exercises a special action upon the coloured portions of the proof. Every photographer must have been struck with the peculiar tone presented by proofs fixed by ammonia, which always exhibits itself under whatever state the ammonia has been employed in the course of the process. It is true, that the swelling of the sizing by the ammonia, and consequently the hydration of argento-organic material, readily explains why the violet hue changes into a red hue; but it does not explain why the hue of the combination so produced is distinctly different from that obtained when the fixing is performed by hyposulphite of soda, for example. The following facts will doubtless account for this interesting phenomenon.

When we expose to the light a liquid containing chloride and nitrate of silver, starch and ammonia, there is formed, as upon the proof, a compound of silver and organic matter; but this compound contains ammonia.

If we take the argento-organic matter obtained by the contact of chloride of silver, nitrate, and starch, and after "fixing" it with hyposulphite of silver, let it become quite dry; then put it in contact with ammonia, it immediately changes its colour, and takes that assumed by proofs fixed with ammonia. If, after repeated washings, we examine the precipitate thus obtained, we discover that it contains ammonia in a state of combination.

Lastly. A proof fixed entirely in hyposulphite of soda, then immersed in ammonia, changes in hue, and assumes the tint of a proof fixed in that alkali.

These facts are conclusive: they prove that in the process with ammonia, this base interferes in a special manner, combining with the argento-organic matter, at the same time it affects the fixing, and consequently, like a dye, influences in a particular manner the colouring of this substance.

Ammonia, therefore, leaves in the proof a small quantity of its substance. This result is important, inasmuch as it explains the peculiar colouring of the proofs fixed in this manner; but with respect to alteration, the quantity of ammonia fixed upon the proof appears absolutely insignificant.

(*To be continued.*)

Meetings of Societies.

BLACKHEATH PHOTOGRAPHIC SOCIETY.

THE usual meeting of this society was held on the 19th ult., at the Golf Club House, when, after the ordinary formal business,

Mr. SKAIFE read a short paper on *Photographic Instantaneity*, by way of introducing to the meeting his new photographic instrument, which he calls a Pistolgraph. After explaining its construction, the inventor gave a practical illustration of its working, by taking two or three rapid photographs of one of the gaslights. All of the plates which he excited, developed, and fixed, was by plunging each successively into three little jars, containing one ounce and a half of fluid each. He then explained how, by superposition, a transparent positive was taken sufficiently defined to yield by one operation of enlargement a *negative* from ten to fifteen times the diameter of the original photograph — half a dozen successful examples of which, plain and coloured, were handed round to the members for their inspection, together with two or three cases of photo-pistolography, chromo-crystallised, inincluding a view of the last Greenwich election, a boat scene on the Thames, and sundry portraits of dogs, horses, and children, the novelty and beauty of which elicited repeated expressions of admiration, coupled with surprise that such a *pistolette* should have been capable of producing them.

To a question put by a member, why the machine was called a pistolgraph instead of a camera, Mr. SKAIFE was understood to say, because, amongst other reasons, the instrument, with the exception of its lenses, had nothing in common with ordinary photographic cameras — so named rather from their outward shape than otherwise to the camera-lucida invented some three hundred years ago by a Neapolitan *savant*.

The CHAIRMAN, in proposing a vote of thanks to Mr. Skaife, observed, by whatever name the instrument was called, its performances indicated a competency to realise more satisfactory portraits of children than any other photographic camera known.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual meeting of this society was held on Thursday, the 19th ultimo, at the Lecture Hall, Carter Street, Walworth; the Rev. F. F. STATHAM, B.A., F.G.S., President, in the chair.

The minutes of the last meeting were read and confirmed.

Mr. G. S. Tear presented two excellent prints from negatives, produced by himself — one, a landscape, by Hockin's modification of the Fothergill process; the other, a portrait, developed with iron, possessing great beauty of definition and softness, but in the drapery only somewhat deficient in vigour.

Mr. Squire presented a set of his recently-published stereographs of sea waves. These were of a very interesting description, representing the tumbling waves in the act of breaking into foam upon a shingly shore.

Mr. Leake, Sen., presented some transparent stereographs.

The Photographic News Almanack: A copy of this useful little work was kindly presented by the Publishers.

A specimen of the society's Presentation Photograph was handed round for inspection. It had been selected by the appointed sub-committee from a very fine collection by Bedford, and was, as a photograph and a picture, equally meritorious. The subject of the print chosen is a view from the eminently graceful and interesting ruins of gothic architecture, Tintern Abbey, and represents the silently decaying grandeur of the beautiful nave arcade, with its tall range of symmetrical pillars and noble arches, half concealed by the picturesque, because not too closely cut, ivy; and its scattered fragments of sculpture and cunning work crumbling into dust amid the grass, weeds, and creeping plants below. The small quantity of white in the picture is in harmonious keeping with the dim religious gloom which, associated with so much solemn glory and departing magnificence, is eloquently expressive. The lightest portions of the picture being massed together on the right, and blending gradually into the more subdued lights and deeper shadows grouped on the left, secures the valuable quality—breadth; nevertheless, the utmost perfection of detail exists on either side; and a painter may find a day's profitable study in every square inch of this very beautiful photograph.

Much satisfaction was expressed upon inspecting the above.

The discussion on Mr. Keens' paper [see page 10], postponed at the last meeting until this evening, was opened by the Hon. Secretary, who said: — I don't know whether Mr. Keens is conscious of having run foul of so eminent an authority as Sir David Brewster, in boldly asserting that "a good photograph will give a faithful representation of the subject with due proportions," but he certainly has. Theory and practice, immaculate apart, when contrasted sometimes reveal contradictions of a very puzzling character; and the present is, I think, a case in point. By careful measurements, we artists have obtained certain scales of proportions by which figures have been drawn universally acknowledged to be accurate representations. Mr. Keens has applied these identical measurements to well proportioned figures produced by photography, and proved to us at our last meeting that they would bear this test. Now, in opposition to Mr. Keens' assertion, Sir David Brewster has emphatically said that the ordinary photographic image is, from the size of the lenses used, *perceptibly* disproportionate — that, to quote his very words, "However perfect the glasses of which its lenses are composed, however accurately the spherical and chromatic aberrations of the lenses are corrected, and however nicely the chemical and luminous foci are made to coincide, the photographic camera is *utterly unfit from the size of its lenses alone* to give accurate representations of living beings, and of all objects in relief, whether single or in groups." Thus, then, stands the matter. Now, gentlemen, I am not competent to treat this question scientifically, but I will nevertheless presume to put forth a few suggestions.

The arguments used by Sir David Brewster are doubtless too well known to you to need recapitulation, and you will at once recognise the points to which I intend my very humbly-tendered suggestions to apply.

In the inconceivably minute fraction of a second light impinges upon the retina, and there forms the images of external objects; but it is not less than the tenth part of a second, I believe, which elapses before a consciousness of the impression reaches the mind. Is it not possible, then, that the lens of the eye, continually varying its aperture (and consequent curve), and by instinctively, or unconsciously, moving from right to left when turned by the will towards any object, may embrace more views, or admit many more dissimilar images, than are generally allowed, and in this case the optical image and the photographic may be more closely allied than Sir David admits. It seems to me, also, that the simple fact of our receiving impressions (by no means identical) through two lenses at a distance of about two and a quarter or two and a half inches apart, has not been sufficiently considered in our great optician's theory. As a properly focussed portrait, taken with a perfectly corrected achromatic lens, does not offend the educated eye, and will bear the test usually applied to drawings for ascertaining the correctness of their proportions, I at any rate shall dare to uphold the truthfulness of any photographic portrait which does not outrage the common principles of our art, and has been taken with the best instruments. With reference to Mr. Quin's diagrams, although Mr. Keens appeared to forget that they could only be applied to objects taken on a plane surface, or lines upon an imaginary plane, they illustrated a very useful optical principle.

The President said, Mr. Wall having opened the discussion, he trusted members would at once take up the subject (which promised to be useful), as they had a paper to follow. Although Sir David Brewster was in theory undoubtedly correct, there was one fact which appeared to be left unexplained, viz., that living objects looked at through lenses (opera glasses, &c.) suffered no apparent distortion, although great distortion, it seems, must exist. He thought a brief *resumé* of the paper under consideration by Mr. Keens would be of great assistance to such members as were not present at the last meeting.

Mr. Keens rose to carry out briefly the suggestion made by the President, and alluded to the inutility of mere theorising when untested by practical experiments.

Mr. Wall had purchased and laid upon the tables several journals for the use of members desirous of referring to Mr. Keen's paper.

Mr. Keens, speaking in reference to Mr. Quin's diagrams, explained the point of sight in perspective drawings as the focus of sharpness, and stated that all objects removed from that point were, in proportion to their distance, out of focus.

Mr. Herve said no photographic image could be absolutely correct not taken upon a curved surface, and recommended curved glasses, as used by Mr. Ross in one of his experiments, explaining the form of the retina in connection with the outer lens of the eye as a reason for doing so.

Mr. Leake, Sen., remembered trying to obtain correct copies of some plans by one of Lerebour's lenses, and then found so much distortion as to render its productions useless.

Mr. Hannaford: A print or mass could not be copied with the ordinary lens: the triplet and the orthographic would give the best copy. With reference to Mr. Quin's diagrams, he thought the experiment would have been more satisfactory had the figure and the photograph been in point of size perfectly identical.

Mr. Herve pointed out the want of sharpness in portions of the lines in Mr. Quin's diagram as evidence of distortion.

Mr. Wall said the question before them was not one of mere sharpness, but of absolute distortion, such as would destroy accuracy of representation.

Mr. Herve: A want of sharpness is distortion.

Mr. Wall: Although the want of sharpness might be, logically and optically, distortion, he still thought absolute distortion, in the sense more commonly understood, was a very different matter.

Mr. Quin did not think indistinctness and distortion one and the same thing, and pointed out in the distorted diagram that parts were very distinct, although distorted, and other parts very perfect in their relative proportions, although not distinct. Mr. Hervé should confine himself to the subject more immediately under discussion, viz., proportion.

Mr. Wall had tried an experiment recommended in one of Sir David Brewster's articles on this subject, by using (with a portrait lens) a stop having five apertures; and, when in focus, the difference between the image produced by the marginal pencils and that produced by the centre — apart from the simple brilliancy ensured by the larger amount of light and some small degree of sharpness — was so slight as to defy detection.

Mr. Herve inquired if Mr. Wall had taken pictures of images so produced, because then they might judge for themselves.

Mr. Wall had not done so, having but little time, and not too much light to spare, for experiments just now.

Mr. Leake produced a diagram which showed the thickening of the lines consequent upon the curvature of the lens affecting the intersection of the rays. In reference to Mr. Quin's assertion about cocking the camera when raised to the breast of the figure, Mr. Leake thought this the proper position for the camera when taking whole-length figures, and explained his reasons by exhibiting a large and carefully-drawn diagram.

Mr. Herve made some remarks to the same effect.

Mr. Hannaford: The most correct proportions were obtained by enlarging from small negatives, which could be best done with the orthoscopic lens, as he thought the inward curvature of the lines obtained by the old form of lens might be corrected by the slight outward curvature of the orthoscopic.

Mr. Quin thought the diagrams being his bantlings he had some right to defend them, and proceeded to state that they were taken very hurriedly, when the light was so bad that he really could not see whether the images on the ground glass were sharp or not; but although the lines were slightly blurred, the proportions of the diagram under discussion were quite perfect.

Several other remarks were tendered, and the discussion grew very animated.

The President thought they might now bring this discussion to a close, and call upon Mr. Leake for his paper. As in the old tale of the chameleon, they were, he thought, all right and all wrong. Mr. Wall had referred to the construction of the eye, and some peculiarities of the sense of vision. In seeing objects we were so greatly assisted by the associated ideas of the mind in arriving at correct notions both of form and surface, that it was difficult to define exactly how much was due to the image formed on the retina. For his own part, he thought he could demonstrate that images received into the eye must necessarily be distorted. The amount of aberration discoverable in photographic portraits seemed to be so small as not to affect their truthfulness to at least any serious extent. As to its superiority in this particular over art, being a clergyman he had frequently been requested to sit for pictures by local artists, and had found that from this source just so many pictures, just so many *un*-likenesses; but photographic portraits, whatever their other faults, were always like.

Mr. Leake, Jun., was called upon to read his paper on *Failures in the Wet Process: their Cause and Cure.* [See page 34.]

At the conclusion of the above paper,

The President said Mr. Leake's failures were, he thought, very successful, and he regretted that so little time remained in which to discuss the paper, and hoped the discussion would be postponed in order that they might study it in detail when printed, and come to the next meeting fully prepared to enter into the subject.

Mr. Hannaford thought in justice to Mr. Leake the discussion had better be postponed, as it certainly needed more time than they could that evening give it. Again, many failures not enumerated might be brought forward at the next meeting, and in the interval some experiments of an useful nature might be tried. Mr. Hannaford then referred to the use of an iron developer, exhibited a specimen of a Fothergill plate developed with iron and pyrogallic, and thought the advantage gained was that it brought out details with greater perfection.

Mr. Howard inquired if this reduced the time of exposure, and how much acid would Mr. Leake consider sufficient in the bath?

Mr. Leake, Jun., thought test-paper was not sufficiently sensitive for the detection of acidity. He had known baths to be acid when test-paper did not change after twenty minutes' immersion. The best way of restoring the bath was to render it slightly alkaline by carbonate of soda, adding acetic acid in very small quantities until a clear result was obtained.

Mr. Tear had used the iron developer with both an acid and alkaline bath with equally good results.

Mr. T. Clarke expressed a similar opinion.

Mr. Hannaford did not think the iron developer reduced the time of exposure.

Mr. Howard agreed with Mr. Leake as to draining the plate. He always got better detail by using iron than pyrogallic alone; and found that in portraits generally there was too much intensity.

Mr. Quin could quite bear out the observations Mr. Leake made in reference to the use of iron in cold weather; but thought the pyrogallic would, in warm weather, develop as quickly as iron. He sometimes found great peculiarities in the quality of light—one light producing a negative best developed with iron, when the pyrogallic was a failure. He thought a weak solution—two grains to the ounce—best.

Mr. Tear considered that an iron developer gave a shorter exposure both in winter and summer.

Mr. Leake, Jun., said the greatest advantage obtained by using the iron was that it enabled you to push the development so as to secure all the details in the shadows without that excessive intensity, destructive of the more delicate gradations, in the lights.

Mr. Hannaford very much regretted that Mr. Hughes was not present, as he had heard that gentleman at the North London Association make some remarks upon the iron developer which were the best he had yet met with; and hoped that Mr. Hughes would be present at the renewal of this discussion.

Several gentlemen promised to bring specimens of failures at the next meeting. A vote of thanks was awarded to Mr. Leake, Jun.

The President then announced that a paper had been promised by Mr. T. Clarke upon the improvements recently made in photographic apparatus, and invited any gentlemen present, whether members or not, to bring down to the next meeting any specimens of improved apparatus they might possess.

Mr. J. R. Silstone was duly elected a member.

A vote of thanks having been awarded to the chairman, the meeting then adjourned.

LIVERPOOL PHOTOGRAPHIC CLUB.

The second meeting for the current year was held at the residence of Dr. Cauty. There was a full attendance of members, and the *séance* was graced by the presence of several ladies.

Mr. Cook, in confirmation of his testimony in favour of waxed-paper at the last meeting, brought with him a portfolio of his negatives, selected at random from his ordinary stock, and a better production could not have been desired: for clearness of outline, minuteness of detail, and translucence of the medium, they certainly left nothing to be wished for. The heaviness of glass, with its brittleness, and its unlucky uncertainty of preservation in other ways was fully expatiated on by Mr. Corey, who related that the whole of his last stock of beautiful negatives of Furness Abbey, which were only taken last September, on being recently examined, were found split up into those arborescent form for which some kinds of varnish were so detestably famous, and were irretrievably spoiled.

Mr. Cauty exhibited some very fine specimens of prints, from enlarged negatives, taken from microscopic objects by Mr. Wenham; and these were pronounced to evince great progress in the utilitarian principle of photography, as those to whom the luxury of a microscope was denied could see the structure of the most infinitesimal objects with the naked eye. The *navicula angulata*, the delicate markings on which none but the highest-priced instruments could reveal, was enlarged to the size of an egg; the *antennæ* of the moth the tongue of the spider, the teeth, or, more properly, internal structure of the gizzard-like organ of the tadpole, were beautifully displayed, whilst laminated sections of the spine of the hedgehog, and tooth of the rat, showed the structure of their osseous condition wonderfully well.

Very great interest was excited by the exhibition of a large collection of plates by the long-neglected and ill-appreciated process of Daguerre. Mr. W. G. Helsby, who had resided for a long time in South America, had brought some truly brilliant reminiscences of his sojourn there. They are all full-plate size, and remarkable for their high finish and perfect preservation. He took occasion to point out that there was no process at present known that was equal to the Daguerreotype for the delineation of every salient point in the perspective, however distant or near at hand; and certainly many of the sierras were represented in their wild and trackless vastness with frightful fidelity.

Arequipa, a large city at the base of a volcano, was beautifully and tastefully rendered, with an evening light, artistically chosen, gilding all the prominent buildings; Tia Yuanaca, a flourishing city, but which was known previously to have existed as a vast ruin, three hundred years before the invasion of the Spaniards; Puno, a city of Bolivia, with its church built by the Jesuits from the ruins of the original Yuanaca, where the natives were in so deplorable a state of destitution that the fee of one dollar demanded by the ecclesiastics for the burial of their dead was beyond their means, while a very unhealthy season with its consequent sickness, and concomitant death was raging. A striking contrast was afforded by the halt of the caravan in the wilderness, with only a few roofless walls of loose stones to protect the wayfarers from the bleak driving wind, and the comforts of the yard of Jack Brothers. In this picture the ordinary beast of burden, viz., the lama, a large and somewhat spiteful animal of the goat or rather alpaca tribe, excited great attention. Much regard was also given to the frozen lake, Las Lagunillas, 13,000 feet above the level of the sea, the waters of which are unceasingly chained up in "thrilling regions of thick-ribbed ice," the warmest day in summer having power only to dissolve the charm at its merest edge, and for only one hour in the day.

Mr. Forrest congratulated the members that after long continued efforts he had succeeded in establishing a recognised position for the art of photography among the fine arts in Liverpool. He had persistently represented to the Liverpool Academy the strong claims there were for a certain portion of their exhibition of choice specimens of this art; but with no satisfactory result. The Society of Fine Arts, however, had favourably considered his appeal, and allotted a certain portion of their wall space in the forth-

coming spring exhibition, and he now called upon the members and practitioners of the art at large, to aid him manfully in upholding its dignity, by sending for the purpose their choicest specimens. He would be happy to afford particulars on application.

A resolution, received with acclamation, to accept Mr. Bell's invitation for the next meeting, closed a delightful evening.

CHORLTON PHOTOGRAPHIC ASSOCIATION.

The usual monthly meeting of this Association was held on Wednesday, the 11th ult. Mr. Nicholson, Vice-President, occupied the chair. The minutes of the last meeting were read and confirmed; two gentlemen were then elected members of the Association; after which

The Chairman announced that the next business would be Mr. Hooper's paper.

Mr. Hooper having made some preliminary remarks on the superior advantages for out-door photography, which processes on paper possessed over those in which dry glasses were used, in respect of portability, &c., thus proceeded :—

On the Turpentine Waxed-paper Process.

Having been requested by several members who have seen the pictures obtained by me with the turpentine waxed-paper process to give the society a short account of my operations, let me remark that I do not come forward as the claimant of some new and grand discovery, but simply to lay before you in detail that method which, after long experiment on nearly all the paper processes which have been published, I find gives me the most uniform and satisfactory results.

With several of the formulæ I have been able to obtain fair negatives, but most of them gave thin skies and were very slow in the camera. It therefore became desirable to obtain an increased sensitiveness, combined with density; and I am glad to say that in these respects, I have succeeded. I will not occupy your time by entering into the details of my experiments, but proceed at once to state how first-rate negatives are to be obtained by the turpentine waxed-paper process.

Almost any paper will answer; but I find my best negatives are on papier saxe, and that can be got of a good quality from any respectable dealer in photographic apparatus. Having selected the paper, cut it to the size required, and mark it at one corner on the right or smoothest side with a pencil, as it is important in the iodising and sensitising operations to float the marked side first on the solution before immersion.

The first iodising solution I make, as recommended by Mr. Sisson, by dissolving one ounce of wax in twenty ounces by weight of turpentine or camphine. I prefer the latter. *Pure* wax can be had from Messrs. Brecknell and Turner, Haymarket, London. Place the bottle containing the wax and camphine in hot water, or in a warm situation, until all the wax is dissolved; then allow it to get cold, filter, and add by small portions at a time two drachms of pure iodine (the addition of castor oil, recommended by Mr. Sisson, I omit). After standing a few days, some wax will probably be thrown down. This only requires to be filtered out, and it is then ready for the first iodising of the papers. A porcelain dish, with a flat bottom, answers for this purpose. The solution is poured into the dish, and as many papers immersed as it will cover. Glass rods should be used for immersing the paper in this or subsequent operations. When a sufficient quantity have been immersed at once, turn them all over together, so that the first put in will be at the top. They are then taken out one by one, and hung up by a wooden clip to drain over the dish or any convenient receptacle, and when sufficiently drained suspended in a place free from dust to dry. The dish has only to be emptied, drained, and tied up in paper to guard against dust, &c., to be ready for use at any future time, without any preliminary cleaning, which, if really necessary, would be difficult to accomplish.

When dry, the papers are ready for the second iodising, the solution for which is composed as follows :—

Serum of milk	20	ounces.
Iodide of potassium	420	grains.
Bromide do.	60	„
Chloride of sodium	20	„

And iodine a sufficient quantity to give it a dark sherry colour. First float and then immerse eight or ten quarter sheets. No greater number should be placed in the quantity of solution named at one time.

It is not necessary to filter this solution, but care must be taken not to pour into the dish any sediment there might be at the bottom of the bottle in which it is kept. Air bubbles are to be avoided in this and all subsequent operations.

The papers may remain in this iodising solution from twenty minutes to one hour, after which take each out separately, slightly drain, then blot off in a blotting-paper book; one such book, with about twenty-four leaves, can be used any number of times, and will serve a whole season.

I have used papers that have been iodised this second time above twelve months, and do not find that they deteriorate by keeping that length of time: this is an advantage, as a stock may be prepared in winter for the next season's work.

Papers thus prepared are ready at any time for sensitising.

The solution for this operation is composed of—

Water	10	ounces.
Nitrate silver	400	grains.
Acetic acid	2½	drachms.
Lemon juice	1½	„

To be *saturated* with iodide of silver.

The dish I have used for the second iodising I also employ for the sensitising, and for no other purpose.

To sensitise a paper, float it on the sensitising solution, face downwards, until the dark colour the paper acquired in the second iodising begins to disappear, then either immerse or turn it over, so as to bring the other side in contact with the sensitising medium; as soon as it has acquired an uniform primrose colour take it out, slightly drain, and place it in a dish containing four ounces of water for every quarter of a sheet intended to be sensitised; thus supposing six papers of the size stated are required, pour twenty-four ounces of water into the dish, and at once immerse the slightly-drained sheet, in order to wash off the excess of silver, and make the paper keep better; sensitise another as before, place it also in the washing dish, and proceed in this manner until the six papers are in the twenty-four ounces of water; shake the dish well after the immersion of every sheet, so as to thoroughly wash the paper; they are then to be transferred to another dish containing the same quantity of water, and well washed as before—drain, blot off in a blotting-paper book (which will serve a whole season, like the iodising book), hang up, and when dry, they are ready for exposure. The same caution must be observed with respect to keeping white light from these papers, as with a collodion plate, the paper when wet being extremely sensitive. To prepare the papers for exposure, wafer them by the corners to some Bristol board, and place them at once in the dark slide. With the washing I have named the papers will keep eight or ten days in summer, and much longer in cold weather.

The exposure required with a lens of sixteen inches focus, and five-eighths stop, will be from seven to twenty minutes, depending on the light and object.

To develop float the paper on a two-grain solution of gallic acid, with one drop of a thirty grain aceto-nitrate solution added to each ounce, until the details of the picture begin to appear, then immerse it; and if there is more than one to develop, as soon as the first is immersed float another, and proceed as with the first: in ten ounces of solution four-quarter sheets may be developed together. As soon as all are immersed, add a few drops more of the aceto-nitrate; the pictures will then intensify rapidly if properly exposed in the camera. When sufficiently intense, wash and fix as usual.

The papers being impregnated with only a small quantity of wax in the first iodising, it will be necessary to re-wax them when finished in the manner generally recommended for the ordinary waxed-paper process. I would recommend amateurs who have never tried any paper process, but who purpose following this out, to prepare only small papers, say stereo size at first, and print on them from a negative by gaslight in the pressure frame, until the picture is slightly visible, and then develop. As soon as accustomed to the small size, prepare larger, and proceed to out-door photography.

It would also be advisable to have a large bottle containing salt and water, into which waste silver solutions washings of baths, &c. (not solutions containing hypo' or cyanide), should be poured, and the resulting chloride afterwards reduced. The waste prints and clippings should also be set aside, burnt and reduced to metal. It is astonishing the amount of silver that may be thus saved, even by those who, like myself, do not follow photography professionally. I have here eight ounces of pure silver saved by the first method, and one-and-a-half ounces from clippings of positives, experimental negatives, &c. I would also lay great stress on the necessity of using clean dishes for sensitising, developing, &c. In the process I have described, with clean dishes and proper exposure, failure is impossible.

Mr. WARDLEY took objections to some of the details expounded by Mr. Hooper. Extra trouble was involved in this process as compared with the waxed-paper process. He considered the employment of camphine was needless as a solvent for the wax, the paper still requiring waxing after fixing, which was performed in one operation in the old waxed-paper process. He also thought the iodising solution too strong, as it involved the use of an unnecessarily strong nitrate of silver bath; he also considered that cyanide of potassium was required in the iodising solutions, as it rendered the wax more permeable to the solutions, and increased sensitiveness was obtained thereby. He preferred the serum prepared by acetic acid to that prepared by lemon juice, believing that an acetate of potash or soda was formed in the serum, which, combining with the nitrate of silver, formed an acetate of silver, which becomes an accelerator.

Mr. GRIFFITHS thought there was no acetate of soda or potash formed, as there was no soda or potash in an uncombined state in the milk with which the acetic acid would combine; he thought there might be other chemical action to account for the increased sensitiveness which it was alleged took place.

Mr. HOOPER, in reply to Mr. Wardley's objections, stated that by using camphine as the solvent the purest part of the wax only was retained in solution, the impurities being thrown down, and this he believed was the chief element of success in this process, as it obviated the granulated appearance complained of in the other method of waxing, which he thought arose from the filling up of the pores of the paper with crude wax, thus necessitating the use of cyanide of potassium to enable the solutions to penetrate the substance of the paper. As to the strength of the iodising solution, that might be reduced one half, but the exposure would be nearly doubled in consequence, and if care be taken to preserve the washing and fixing solutions, no extra loss of silver is sustained. He admitted that Mr. Wardley had produced excellent pictures by his method of working, which he attributed to his skill in manipulation, whilst by the method he advocated equal results might be obtained by less practised operators.

Several other members having spoken,

Mr. WARDLEY paid a compliment to Mr. Hooper for the success of his experiments, and for his interesting paper, and begged to move that the thanks of the meeting should be given to that gentleman, which was seconded, and carried unanimously.

A vote of thanks was also passed to Mr. Nicholson for his conduct in the chair.

Mr. Wardley exhibited twelve very beautiful views in Manchester, taken by him for the lanthorn, published by Mr. Mudd, copies of which are now being exhibited at the Mechanics' and the Pendleton Exhibitions. The negatives were taken on collodio-albumen, and the prints by the raspberry syrup process.

Mr. Rogerson also exhibited some prints taken by him during the recent frost, which he had polished very highly, from a formula lately published.

Exhibition.

LONDON PHOTOGRAPHIC SOCIETY'S EXHIBITION.

THE Seventh Annual Exhibition of the Photographic Society was, as intimated in our last, opened to the public on Friday, the 13th ult., the private view having been held on the preceding day, on which occasion there was such a goodly gathering of photographers and their friends, that in the course of the day the visitors perhaps outnumbered the works exhibited, and, in consequence, there was not much possibility of seeing to advantage: there was, however, no lack of something to be heard.

The first thing that strikes one on entering the room is that, in returning to the old quarters occupied by the society for several years in succession (until the last two), we have literally come back and can almost fancy the collection to be the same as we last saw there, so familiar is the aspect presented by the general arrangement of the room. There are, however, on the present occasion but very few striking pictures that stand prominently forward from amongst the general mass; yet it must not be supposed from this assertion that the collection is not a good one — on the contrary, it is precisely because the whole collection is generally highly meritorious that the absence of any markedly striking feature is felt. We must, however, make one exception with regard to this statement; for the place of honour at the west end of the room is occupied by a production that is certainly conspicuous in a pre-eminent degree, we mean (No. 338) a copy of the cartoon, *Paul Preaching at Athens*, photographed by C. Thurston Thompson, and coloured by J. S. Morgan so as to resemble the original before the colour was partially destroyed by age. This picture is upon a very large scale, and as an illustration of what can be effected in this way by the aid of photography, is truly valuable; in fact, it shows us how, by a judicious combination of science and art, we may rescue many invaluable works from nearly total seclusion, and, at the same time, goes far to enable us almost to bid defiance to the destructive hand of time; for just as the printing press preserves the spirit of the manuscript so does this new application of the camera and the pencil preserve the spirit of the painting, in producing copies too numerous and, consequently, too widely diffused to allow of their running much chance of total extinction.

We have often before had occasion to deprecate the abuse of the brush with regard to photography: it is therefore with the greater pleasure that we feel able to recognise its legitimate application. We cannot refrain also from noticing Mr. Thompson's good taste in not attempting to overdo a good thing. This single specimen is more effective than a dozen of the same tribe would be, and where the size is so large, the space required is an important consideration. No one can grudge it for the one fine specimen; but with a room of such moderate dimensions as that occupied, a greater number of the cartoons, even if as well executed as the one under consideration, would have been embarrassing. Mr. Thompson's moderation is therefore satisfactory as well as graceful.

The general arrangement of the works does credit to the hanging committee. There are, however, some very meritorious specimens that occupy but indifferent, not to say bad places. Some of them we shall have to notice hereafter, when we can manage to see them; but on making inquiries of the custodian of the collection, we were informed that the works so placed were not sent in until long after the last day fixed for receiving contributions, and most of them not until after the arrangement of the pictures was completed and the catalogue partly framed. Under these circumstances, though we are sorry that works deserving a better situation should be so placed that they can only be imperfectly seen, we do not think that the producers can justly complain. They have only themselves to blame; for it would be simply *impossible* to re-arrange the whole at the last moment, even if those who have devoted their gratuitous labour and valuable experience to the performance of an onerous and thankless duty were inclined to do it. There is one suggestion which we would offer to the gentlemen of the hanging committee: that to exonerate themselves from want of due discrimination, they should append a *label* to all specimens that have been thus unavoidably badly placed for examination, indicating the unreasonable lateness of time at which they were sent in. It is our opinion that had they been altogether excluded the committee would have been quite justified in such a decision, and their being included at all should be regarded as a concession.

It is with considerable satisfaction we observe that the printing of the several productions is of a high character: this has been more and more noticeable at each succeeding exhibition, and tends to display the growing conviction of the great importance of this part of the manipulation. We also recognise the fact that there are more lady exhibitors than have ever hitherto favoured us, and we think there is not improbably some connection between the two circumstances. Photographic printing is an employment peculiarly adapted for female industry, and when once sufficiently interested in the occupation to undertake it, it is not surprising that some at least of our *photographic sisters* should like to try their skill at producing negatives. It is with much pleasure that we welcome them amongst our effective volunteers. We may here remark, *en passant*, that one of the most beautiful landscape pictures in the exhibition (No. 463) is the handiwork of a lady.

We would recommend for the future the addition of some initials at least to the intimation as given in the present catalogue, which merely indicates—"by *a* lady." The regulations require the *name* of the photographer; and though we are quite willing to admit that ladies should be entirely at liberty to withhold their names if they please, it is rather puzzling when we find works evidently by different hands described in the same manner. This will no doubt suggest itself to the fair exhibitors for the future; the intimation simply "by a lady" being evidence of the novelty of the position—each one of course supposing that it would be a sufficient distinction.

We will now proceed to take a rapid glance at the various works. Time will not permit us to review in detail more than a fraction of those that deserve special notice, the average of excellence being, as we before stated, very high. We shall therefore content ourselves on the present occasion with general rather than particular remarks.

Amongst the veteran contributors we observe the names of Bedford, Fenton, Gutch, Hennah, Lyte, Morgan, Robinson, Rosling, Thompson, Williams, &c., &c. But several old friends are altogether unrepresented. For instance, we miss the thoughtful productions of Rejlander, the charming rural scenes of Turner, the finished studies of Llewellyn, and many others for which we naturally look; but on the other hand we have some new recruits.

Occupying the post of honour at the east end of the room, and exactly facing the cartoon before noticed, we find a mass of Mr. Fenton's charming landscapes, &c., of which we may mention particularly (No. 134) *The Keeper's Rest, Ribbleside*, which displays a wooded nook beside the river, where the guardians of wood and stream are assembled for their mid-day refreshment; it is altogether a refreshing picture. Nos. 131 and 142 are companions, and are both excellent subjects, but not given with Mr. Fenton's usual ability. No. 120, however, is on the contrary a perfect gem: it represents a portion of *The Cloisters, New College, Oxford*, and is very artistic in its treatment. No. 121, *The Lily House, Botanic Garden, Oxford*, deserves especial commendation, and is not only a picture but a valuable botanical illustration. The two last are of smaller dimensions than most of Mr. Fenton's works, but of a size that we very much prefer. We think, also, that they are on this account more likely to attain a much larger circulation than those of very great size.

We notice also that Mr. Fenton has been unusually successful in copying a painting by Lance, as exhibited in No. 116, where the equivalent of colour in light and shade is very happily accomplished. "May his shadow never be less!"—not an inappropriate sentiment towards a landscape photographer, as it presupposes the presence of sunshine.

Mr. Henry White exhibits some very carefully-executed landscapes of large sizes. No. 155, *The Wheat Field*, and No. 115, *Scotch Firs*, struck us as favourite examples, in which pleasing subjects are rendered with plenty of nice half-tone and well posed.

Mr. Bedford charms us as usual with his highly-finished cabinet-picture style. Our especial favourite is (No. 238) *Moel Siabod, at Capel Curig:* the distance especially is exquisitely rendered. (No. 216) *View at Aber*, (217) *Pont-y-Pair*, and (227) *View at Capel Curig*—all in North Wales—are decidedly above the average, that is, Mr. Bedford's average, and consequently super-excellent.

We are pleased to observe that Mr. Bedford has taken two views in Chester, one in Bridge Street, the other in Eastgate Street. Chester is a very picturesque old town, and affords abundance of "food for the camera," but somewhat difficult to get at, owing to the extreme narrowness of the streets.

Conway Castle seems a very favourite subject, if we may judge from the frequency of its occurrence. We have it by Mr. Bedford (in No. 225) from a more picturesque point of view than usual. There are two illustrations of it by S. H. G. (a Liverpool lady, as we are credibly informed), Nos. 63 and 306, both beautifully printed from very fair negatives. We scarcely remember an exhibition of photographs in which *Conway Castle* has not figured. It is something like the *Finding the Body of Harold* amongst the knights of the palette.

Mr. John H. Morgan, of Bristol, whose exquisite productions we have several times noticed on former occasions, contributes many beautiful landscapes, &c., amongst which we prefer No. 90, *View near Chagford*, a lovely combination of wood and water; No. 93, *The Cart Shed*, a capital study; and No. 465, *View at Aber*. This last is taken from a spot not far from that chosen by Mr. Bedford (No. 216); but let those who deride photography as a mechanical art look at the two and own that the impress of the individual is undeniably stamped on each. Both are excellent, yet how different the treatment! The two gentlemen named appear to have been following much the same track during the past season.

Messrs. Ross and Thompson, of Edinburgh, have furnished some of their valuable studies of what we may call roadside plants, as No. 80, *Marsh Coltsfoot*; No. 95, *Hemlock*; No. 305, *Reeds and Water Plantain*. These are botanical illustrations, artists' studies, and pictures, all in one.

Mr. Henry P. Robinson, of Leamington, is the principal contributor of figure subjects. We have already mentioned that he is to be the recipient of the Prize Medal of the Photographic Society of Scotland, for his group designated *Here they come!* (No. 429), a well-posed group of two peasant girls on a moorland, one of them being prone on the heath, the other wearing a sun-bonnet, and shading her eyes with her left hand, while she is looking eagerly for the coming of her expected companions. There are several groups that we have before noticed in these pages at length, as well as many new ones, amongst which No. 504, *Studies*, No. 447, *The Lady of Shalott*, No. 459, *A Cottage Home*, No. 462, *Lavinia*, are deserving of attention.

We mentioned in the earlier part of this notice that there were several lady exhibitors. On the screen next the door there are four which we judge to be by the same hand, though of very different degrees of merit. No. 412 is under-exposed, but No. 413, *Village Carpenters*, is very good in manipulation, though the pose is a little stiff and formal. No. 390, *Interior of a Church in Salop*, affords evidence of future promise in the operator.

Mr. F. M. Lyte displays a goodly number of his continental gems—some fifteen or sixteen we reckoned, perhaps there are more —all good, some perfectly beautiful, as, for instance, No. 448, *St. Jean-pied de Port, Haute Pyrénées*, in which there is a combination of sky, water, and, above all, *atmosphere*, that cannot fail to delight the eye of an artist. No. 436, *Le Chaos de Gavarnie*, No. 96, *Le Pas de l'Echelle*, and No. 172, *Le Pont de Bétharram*, are, perhaps, amongst the extra charming ones.

No. 488, *Near Coniston, Lancashire*, by James Mudd, of Manchester, is an exquisite landscape, in which the distant hills are beautifully softened by the intervening atmosphere; the waters leaping from rock to rock are transparent; and the whole subject is well chosen and as well executed. This is the picture which wins the prize medal at Edinburgh in the landscape competition. We notice that it is by the collodio-albumen process. We have several others of Mr. Mudd's productions to notice, but as they are mostly by a dry process we shall postpone any further mention of them until a future number, as we wish to contrast them with others also by dry processes, and treat of the whole of these together, as they do not hold a place one whit inferior to those from moist plates, when considered *en masse*. Amongst those to comment on we have reserved some very fine pictures by Mr. Rosling, Mrs. Verschoyle, Mr. Sykes Ward, Mr. Melhuish, Mr. S. Bourne, &c. &c. With regard to the last-named, we perceive with much satisfaction that he has made wonderful progress since last year in *artistic* excellence: his manipulation was then of very high character, and, if we remember rightly, he only missed securing the prize given by the Nottingham Society in consequence of the pictures he sent in for competition being somewhat deficient in this quality. Should that circumstance have directed his attention to the failing, the apparent loss will have been a positive gain of no slight value. We have not half exhausted our notes, but the length to which we have already extended this notice warns us for the present to close our observations.

Practical Instructions on Coloring Photographs.

By Alfred H. Wall.

CHAPTER VI. *(Continued.)*

BRINGING OUT THE HEAD.

You have now secured the principal features, but before proceeding examine your picture side by side with a good untouched print upon albumenised paper* to convince yourself that the true form and expression have not been in any degree destroyed. The greatest difference should be found in the increased transparency of the shadows obtained principally by strengthening the "reflections," and a greater force of effect in your "touched" picture.

THE PRINCIPAL LIGHT.

A well-lighted head will have the highest or brightest light upon the top of the forehead, and the faintest upon the chin, and between them the high lights will graduate according to the prominency of the surface upon which they fall. This rule should never be lost sight of. The light upon the forehead is brightest because nearest to the illuminating point; and that on the chin faintest, because farthest from the same. In treating all lights, therefore, proper subordination to that which is the principal becomes of great importance.

REFLECTIONS

Constitute one of the most important elements of roundness.† The following experiments will do more to illustrate this, and impress it clearly and forcibly upon your attention, than all I could write upon the subject.

* Prints upon albumenised paper invariably give more detail and better gradations.

† A point which I have, in a preceding chapter, strongly urged upon the attention of photographers, who have sadly neglected this source of beauty and effect, and thus originated in the minds of clever men, not practical photographers, a belief that the power of our art is so limited as to be unable to secure the proper order of artistic effects. See the article I have before referred to in the *Quarterly Review*.

Take a white globular form and place it in the direct light from any aperture. Where the rays of light fall you will of course find the "highest" or "principal light," and from this point the tone of the surface will deepen in proportion to its receding character until where it becomes darkest; it will again graduate into a shining reflected light.

This reflection will, however, by contrast, appear much stronger than it really is, and to prove this try another experiment.

Lay a roll of writing paper on a piece of white card immediately before a window, and bend up the card on the side farthest from the light until you get the reflection as *strong as possible*, then compare the reflected with the direct light, and you will immediately see how great a difference exists in their relative strength, or power.

Reflected lights will be found near the extreme edge of the shadows on the side farthest from the illuminating point, and in or near the centre of such shadows as are formed on surfaces shielded by their projection from direct light.

With the utmost attention to the preservation of the photograph, then judiciously strengthen the reflected lights by touching tenderly upon the masses of shadow, modelling with the same faint touch until the head begins to assume the roundness of a marble bust.

BLACK AND WHITE AS LIGHT AND SHADE.

Considering the form of the head as very similar to that of a globe, you will at once understand how small a portion of its surface is exposed to direct light; and as this portion of direct light must be represented with white, it will be apparent to you that such photographic portraits as are nearly all white (as but too many are) must be thoroughly false to nature. Take white as representative of your highest light, black as the representative of your deepest shadow, and between the two blend as many tones as will give (nearly as possible) that insensible gradation from light to shade which exists in nature. Many photographers, either by the printing, exposure, or developing, absolutely *endeavour* to produce the flat effect obtained by too great a preponderance of white, and it is only on such pictures that the process of touching becomes a positive necessity; for if they (the operators) will not or cannot get truth in the camera, as they certainly may, they must from the brush.

METHOD OF WORKING — WASHING.

In applying the first strengthening tints, do so with a few *faint* "washes," avoiding either too full or too dry a pencil, calculating the space you have to cover, and taking up just enough colour to do it with, using a small or large brush according to the quantity required. Your "wash," as colour so applied is called, cannot be too pale, although it is bad policy to repeat this process frequently, because it disturbs the surface of the print. A small piece of paper may be placed beside you to test the strength of your tint before applying it to the photograph. Let one tint be lost in another as gradually and imperceptibly as you can. In graduating a wash, either take up water or colour, according to your desire, whether it be to graduate it from pale into dark or the contrary. In graduating with touches, do so by repetition, carefully observing the minutest gradations, and using but little colour.

The first wash should be allowed to dry before the application of a second. If it prove too dark wash it with clean water and absorb the moisture with clean blotting paper.

The author of the preceding paper has, in order, to render his communications of greater practical value, kindly undertaken to criticise the work of, and give advice to, students in colouring, through the medium of these pages, for which purpose specimens may be sent, with a stamped and directed envelope *for their return, to* A. H. Wall, Esq., 11, The Terrace, Walworth.

James Williamson (Hammersmith). — Such advertisments only serve to entrap the thoughtless and unwary, and are more serious in their consequences than many imagine. Several poor girls, anxious to secure a genteel and comfortable livelihood, with but very few pounds to spare, have, to my personal knowledge, been induced by these enticing quacks to expend their little all in supporting themselves while receiving the half-dozen or more lessons for which the greater portion of their trifling capital was expended. Photographic colouring is an art by no means easy to acquire; and much time and study must be devoted to it before the student will be in a position to earn a shilling thereby. I know there are those who fancy the colouring of a photograph and the colouring of an engraving demand about the same amount of skill and knowledge; and many hand-books of photographic colouring strengthen the notion by their thoroughly unartistic character, and the studiously unpretending nature of the instructions given. You will easily understand that a little can be taught in less time and with fewer words than are required for the ample details and carefully explained particulars, which alone will insure the honest teacher and the earnest pupils success. I *do* believe that these instructions, and the advice and criticism I have proffered in individual cases will, and I am sure ought, with practice, to make really good photographic colourists.

Correspondence.

☞ We are at all times willing to assist our Correspondents to the utmost of our ability, but we can only do so through the medium of the Journal. We cannot give private replies except to personal friends.

ENLARGING.

To the Editor.

Sir,—Please oblige me with a mode of enlarging photographic portraits from small ones by the means I possess, namely, a *whole, half,* and *quarter size* camera, with excellent lenses. I cannot afford Woodward's solar camera, which I have heard so much of, but I feel assured with your vast knowledge of such matters you can help me. My object is to produce a print sharp and vigorous, the *head to be five inches*, and a small portion of the shoulders. My large camera does this *badly: every part magnified.*

My apology for thus troubling you is that I live 400 miles from civilisation, but your Journal gives me many valuable hints

Cork, Jan. 16th, 1860. I am, yours, &c. E. J. H.

[Take your negatives with your *smallest* combination, develop with an iron solution, and do *not* strengthen its intensity, but aim at producing a negative full of detail but *weak*, and such as would not print well upon paper.

To enlarge from this, put it into its original position in the small camera, rack out the lens a little farther, remove the lens of your largest camera, and place the two face to face, drawing out the larger one to its full extent, and if need be lengthening it by attaching some light-tight materials between the lens of the small camera and the opening of the larger one. Fix the two in position on a piece of board, and turn the whole upwards towards the sky, presenting the back of the small camera towards the light; the shutter must be drawn up, and the back lid opened to allow the light to pass through the negative; then focus carefully, and having done, so shut off the light while you replace the focussing-screen of the larger camera with the sensitive plate. Expose and develop, &c. as usual; a transmitted positive will result, from which, if desired, a negative may be taken by printing on a dry plate. There is here, however, a good field open for applying a suggestion of M. Poitevin's noticed in our Leaders of 15th December and 1st January last, which see.—Ed.]

LARGE PORTRAITS.

To the Editor.

Sir,—In the number of your Journal of January 1st, there is a short notice of the Exhibition of the Scottish Photographic Society, now open in Edinburgh. The writer of the notice has slipped into two errors *regarding us*, which, with your permission, we would now correct. The article states: "In this year's Exhibition there are some very large portraits — that is, *enlarged;*" * * * "but in these I find no appearance of progress." What we object to here is the explanatory words, "*that is enlarged.*" We exhibit the largest portraits in this collection, or, for that matter, ever displayed in any exhibition, and *they are* not *enlarged.* Nos. 111, 298, 695, are ordinary prints, each occupying a complete sheet of photographic paper. They are from collodion negatives, and are half-life size, and were taken *directly from life* during the month of November last. But for the fear of trespassing too far on your space we would feel disposed to describe somewhat particularly the lens and camera used, exposure given, &c., in producing these pictures. However, if you think well of it we can do so at a future time.

Anent your correspondent's *opinion* that in this there is "no progress," we say nothing; but if our other engagements and the present scarcity of light permit us to get passable copies printed soon, we will have pleasure in forwarding to you proofs from the same negatives, quite *untouched* as are those in the Exhibition, and you can then form your own opinion.

One other slight mistake has crept into the notice. We are designated as of Dundee instead of Glasgow. Why do those who get up the Exhibition catalogue omit the residence of photographers in the list of artists exhibiting. In nearly every case they do know, and it may be interesting to the public to know also, and is sometimes absolutely necessary to identify the person. Who is T. H. Morgan? or J. Stuart? There is nothing to indicate that one is located in the north of Scotland, or that the other is domiciled in the south of England.

We are, sir, yours respectfully,

CRAMB BROTHERS.

P.S. The exact size of the pictures referred to above is, respectively:— Nos. 111, 298, are on a sheet of "Towgood," 20 × 16 inches. No. 695 is on "Saxe," and is 23 × 18 inches. C. B.

[The notice of the exhibition named is, as you perceive, from a correspondent, who is in general an acute observer.

We shall be happy to state our own opinion upon the merits of the productions, if we have an opportunity; but we do so (if at all) candidly.

The catalogues are not, as a rule, ever properly got up. The best we ever saw was arranged at Dundee.—Ed.]

LENSES.

To the Editor.

Sir,—In these times of inquiry respecting the best photographic lenses, I think that any information respecting them must be of general interest. It appears that Mr. Wilson, of Aberdeen, to the excellence of whose photographs your last number bears a high tribute, has, in communicating with another periodical, vouchsafed an adverse opinion upon a certain lens. This is a practice so unusual that I rather suspect there is something under the surface which does not appear, and the more so as the editor of the periodical is notoriously inimical to the patentee of the lenses in question. I am personally acquainted with several photographers who, in common with myself, have tried these lenses, and with the best results. Should Mr. Wilson have made any similar communication to you, I think your publishing it, together with any information you can give us on the matter, would be generally acceptable. For my own part, I would place much more reliance on what comes from *neutral ground* than from *antagonists' quarters*. X.

[Mr. Wilson has certainly made no such communication to us, nor should we think it at all probable that a professional artist and photographer of his standing would have *volunteered* any such statement. It must be borne in mind that, clever artist as Mr. Wilson undoubtedly is, he may possibly not be possessed also of much optical knowledge, in which case it is very easy to *misapply* lenses constructed for some special purpose: for instance, such as would be well adapted for delineating the exquisite sunset views we lately noticed, might, and most probably would, be unfitted because not intended for taking architectural subjects without some reduction of their aperture. We make no *assertion* respecting Mr. Wilson's optical knowledge—we are merely supposing a case—but will call his attention to this note, in which case he may, perhaps, be inclined to enlighten us. We may, however, here remark, that we have a very high opinion of the *principle* involved in the construction of the lenses to which you refer, if we understand you correctly.—Ed.]

To the Editor.

The Rev. Edward Leachman presents his compliments to the Editor of the British Journal of Photography, and would call his attention to an error in the Almanack Mr. E. L. has received with this month's number, which if uncorrected may prove a source of perplexity and annoyance to those making trial of M. Poitevin's positive printing process.

In the Almanack it is stated that the prepared paper is to be exposed beneath a *negative*, a statement confuted by the concluding observation that the parts *not* acted on by light are subsequently converted into black gallate of iron.

A careful reader would immediately discover the discrepancy; but as it is just possible that *all* your readers are not sufficiently so, it might be a service to such to "make a note of" the mistake.

The process is very correctly given in the number for July 15, 1859, of your Journal, where it is particularly stated that 'the design' to be copied must be *positive*, for the parts of the paper thus prepared influenced by light are white."

8, *Oakley Villas, Adelaide Road, Haverstock Hill, N. W., Jan.* 11.

[Want of space prevented the appearance of this note and some others in our last.

We are obliged to our correspondent for correcting the error named.

We may be permitted to mention, however, that we are *not responsible* for the Almanack, which we did not see either in MS. or in type till it was published.—Ed.]

CHEMICAL FOCUS—RESTORATION OF COLLODION.

To the Editor.

Sir,—You would much oblige by enlightening me in your next upon the means of how to proceed to make the visual with chemical focus to agree together. I have a Derogy's portrait combination lens, and although the image is perfect (very sharp) on focussing on a ground-glass, I cannot obtain the same on collodion plate after having fixed it.

2nd.—What may be done to increase the sensitiveness of old collodion which has been kept for two years? the colour is a pale sherry, but the sensitiveness is diminished. I see Messrs. Squire & Co. are advertising Collodion-Reviver, may I depend upon it so far as to be certain that my old collodion will not be spoiled by adding this mixture?

I am, yours, &c.,

OLD SUBSCRIBER.

[1. In the specimen of Derogy's lenses which we tested the chemical and visual foci agreed perfectly in all its combinations. If it do not you cannot rectify it except by making a proportionate allowance of distance when focussing; but should the foci really *not agree*, the lens should be returned to the maker.

We have several times described how to test this point by the use of M. Claudet's focimeter or any substitute for it.

The image before fixing should be noticed to see whether you do not render it indistinct by dissolving out a part with your cyanide solution.

2. It will not *spoil* it, though you cannot restore it to its pristine condition. It is probable that the collodion has become decomposed from long keeping.—Ed.]

ACTINOMETER.

To the Editor.

Sir,—Dr. Woods, of Parsonstown, has lately brought before the notice of scientific men and photographers an actinometer, which, from its accuracy, will be, I think, a great boon to the latter. The Doctor states that heat will probably interfere with the perfect working of the instrument, and suggests that a thermometer be placed in the liquid to register the temperature.

Would it not be better to have one bottle with the peroxalate of iron solution, and a second bottle containing water only, furnished with a tube the same bore as the other, and place them side by side?

The expansion by heat would at once be ascertained, and deducted from the peroxalate register would give the amount of actinism.

He also states that the heat may possibly cause the solution to throw off more carbonic acid, and thus cause inaccuracy.

I do not find much difficulty in that respect, and should photographers adopt this instrument, they will, I think, find it sufficiently accurate for their purpose. I am, sir, yours, &c.,

DE ALIENO CORIO LIBERALIS.

Manchester, January 24th, 1860.

[Good! If our correspondent will favour us with a sketch and full particulars of his plans, we will try and induce some of our enterprising photographic instrument makers to get up actinometers for sale at reasonable rates.—Ed.]

OUR INSANE CORRESPONDENT.

To the Editor.

Dear Sir,—Do you know anything relative to the enclosed advertisement?

"If the symmetrical trouble-it lens which was 'so much at sea' in the Scotch waters will return to its disconsolate projector, *all faults will be forgiven*, and *no troublesome questions asked*."

I have been thinking that perhaps there may be some connection between it and the *Favourite Fairy* noticed in your number of Dec. 15, as I observed that she admitted being "*something beside herself*."

I am, yours, &c.,

?

ANSWERS TO CORRESPONDENTS.

*** Foreign Correspondence.—Owing, no doubt, to some postal mishap our Paris Correspondent's Letter has not come to hand before going to press.

Cedo Nulli.—We have no objection.

Cursitor.—Take the *third* on your list.

J. R. A.—You will perceive that we have acted upon your hint.

Zany.—You had better make a new toning bath by Mr. Maxwell Lyte's formula.

Pen Owen.—Consult the "Photographic Glossary" in last year's volume.

Omega.—Hollingsworth's thin paper is best suited for printing on by development.

W. G. Smith.—We have already expressed an opinion upon the instrument named by you. See our last volume, pages 223, 236, and 263.

Focus.—It is too much to expect a lens to answer well for everything. You must limit your operations to what it is constructed for.

S. H. H.—See our Paris Correspondent's letter in last number of this Journal for a portable developer.

Anson. It is probable your bath contains too much iodide of silver; add some more nitrate of silver to it and filter.

J. Watson.—You will find your question answered in the present number. See *article* on "Fixing Positive Prints."

Charles T.—Your nitrate of silver is probably impure; it should be in flat crystals. Nitrate of potash crystallises in needle-like crystals.

A Beginner.—Do not be discouraged with the difficulties that beset you; every failure is a step in experience on the road that all Photographers must travel.

Chrome.—We have seen no specimens of photography in natural colours: it would require the employment of a sensitive salt capable of assuming every colour in nature and art, and other conditions, which at present appear impossible to be obtained.

Enquirer.—We are not aware of the name of the maker of the India-rubber gauntlets, but believe they are to be had of a dealer in waterproof materials, located in the Strand, near Temple Bar, London.

M. D., Crown Street, Aberdeen.—Why use such a barbarous word as "*Stereogram?*" Telegram was an unfortunate necessity, because telegraph was already in use otherwise, but there is no need to inflict such a cacophonous termination on stereograph, photograph, lithograph, &c.

Thomas Barnes.—There are several very good portable operating chambers See the account of Smartt's Tent in our last it is sold by Murray and Heath. Burfield and Rouch have a very excellent one; as also Shepherd, of Farringdon Street, and many other makers.

Tite Barnacle.—We have before now expressed our indignation at the attempted exclusion of cameras from public places (being the property of the public) where there can be no pretence for obstruction It is monstrous. We have on several occasions worked in forbidden places without hindrance, simply because it never occurred to us as being necessary to *ask leave*—indeed, had it been suggested to us we should have scouted the idea.

Received.—"Very Dry"—"F. B."—"E. W. B."—"R. Peers"—"W. W."—"Q."—"Lovell Reeve"—and "T. B. W."

We must crave the indulgence of these and many other correspondents. We are suffering from a very severe attack of illness, and are quite incapable of attending to them for the present, but will do so as early as possible. The same applies also to the reports of meetings, &c., as our attack was too sudden to admit of our procuring extra assistance, or of being in a condition to do so subsequently.

☞ Several articles in type have been omitted for want of space, among which are "Sel D Or's" Second Notice of the Exhibition of the Photographic Society of Scotland, and "Notes of a Photographic Tour in the Holy Land." No. XIII.

☞ *All* Editorial *Communications*, Books for Review, *&c., should be forwarded to the Editor*, GEORGE SHADBOLT, 2, *Upper Hornsey Rise, London, N.*

All Advertisements *and* Letters *on the* Business *of this* Journal *should be addressed to the* Publisher, 32, *Castle Street, Liverpool.*

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 112, Vol. VII.—FEBRUARY 15, 1860.

A document of considerable importance to photographers will be found in another column. We allude to the first report of the Committee appointed by the Photographic Society to examine such specimens of collodion as should be voluntarily submitted to it, accompanied by *full details of composition and method of manufacture, without, any reservation*. Before commencing operations an advertisement was published by the Committee announcing its intended proceedings, and inviting manufacturers of collodion to submit their productions to the proposed scrutiny; and it is, we think, much to be regretted that in addition to Mr. Hardwich only two other gentlemen responded to the invitation, and those two failed to supply a sufficient quantity of material to enable every member of the committee to make the necessary comparative experiments. The report now before us is, therefore, confined exclusively to a statement of the results ascertained upon examination of Mr. Hardwich's collodion alone.

The indisposition manifested by the generality of the manufacturers of collodion to respond to the invitation of the Collodion Committee must have arisen from one of the three following causes:—

1st. The non-existence of any definite formula.

2nd. Apprehension lest any formula employed should be found unsound in principle.

3rd. Inability to perceive any advantage likely to accrue from the communication of what may be regarded as a "trade secret."

Of these the last-named is, in all probability, that which has had most influence, and, if so, it is the more to be deplored that any impediment should have interfered with the proper investigation of the other two samples of collodion furnished, together with the necessary information. We cannot help thinking that the Council of the Photographic Society would have willingly afforded the necessary funds to have purchased, if needful, any further quantity, and it could certainly not have been objected to as a misapplication of the Society's funds. Had this course been adopted the Committee would, in all probability, have felt relieved, partially at least, from a little embarrassment under which its members have evidently laboured from having had to deal with only one sample of collodion. This embarrassment is very apparent on carefully perusing the "report," as it may be noticed that the remarks quoted are generally incomplete, and partake rather of a negative character.

It is scarcely to be expected that so numerous a body as that constituting the Collodion Committee would have been unanimous in the majority of the opinions expressed by its several members, and, therefore, in order to include as much unanimity as possible, it would probably be necessary to exclude a very large portion of the remarks of each individual. Now it occurs to us that it might not be at all a bad plan to publish, at an early date, the separate opinions of each member of the Committee *in extenso*, thus following the practice observed in parliamentary committees of giving the *evidence* upon which the reports are founded.

In considering this "report" in its details, we not only find that it affords high testimony to the excellence of the collodion examined, but also draws attention to several points of general interest, not merely with reference to this but to most other kinds of collodion. With regard to the freedom enjoyed by Mr. Hardwich's collodion from liability to putting the nitrate of silver bath out of order, though the Committee, as a body, pronounces no opinion on the cause, certain members attribute it to the exclusive use of pure ether and alcohol instead of *methylated* spirits, as employed by some manufacturers.

This is completely in accordance with an opinion that we have more than once expressed relative to the injurious action that we are convinced is exercised by methylated spirit upon the nitrate of silver bath.

The evidence upon the superior stability of iodide of cadmium as an iodiser is also corroborative of general experience; but, what is of more importance, and that which does not seem to have been so generally recognised, is the fact that a proper admixture of iodides and bromides produces a far more stable collodion, and enables it to render the effect of colour in landscape scenery in truer gradation than when an iodide alone is resorted to. This is a point which was clearly and satisfactorily demonstrated more than twelve months back by Mr. Heisch, and to which we have repeatedly drawn attention in these pages. The numerous questions of importance that have been raised in this investigation, and the nature of the remarks made by several of the members of the Committee, tend to demonstrate clearly the probable advantage that would arise from a series of well-conducted comparative experiments with different kinds of collodion.

We perceive that the name of the editor of a weekly contemporary has been removed from the title-page of the publication hitherto under his management. The fact is significant.

ON THE OPTICAL CENTRE.

By Thomas Grubb, M.R.I.A.

No. II.

If the object at present in hand were confined to that of showing that any optical centre belonging to what I have purposed to designate an "open compound," is not of a fixed nature, but, on the contrary, varies in its position with the circumstances under which the compound is used, a sufficient proof of the same is contained within the limits of two very simple propositions, viz.:—

1st. That the *place* of such a centre must have a relation *to the powers exerted* on either side of that centre.

2nd. That we necessarily alter these powers, *without altering the compound*, by merely making a change in the proportion of the conjugates formed by such compound.

Every photographer or person having within his reach an ordinary portrait combination can, as we shall see by-and-by, test the truth of this practically.

When, however, we are led by circumstances to consider that which had appeared to possess a fixed character to be, on the contrary, *variable*, it becomes not only interesting but profitable to investigate the laws and conditions which affect such changes.

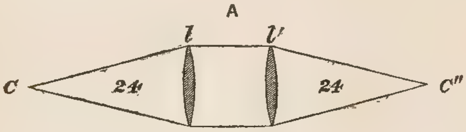
The present case is no exception, and as the examination of the laws which govern these changes afford the best possible proof of the changes themselves, I make no further apology for treating the subject in a general as well as in a popular manner.

Having assumed that no fixed optical centre is to be found in the open compound, I may at once state what is to be found in such, viz., an innumerable number of places (or points) occurring within a certain limited distance in the axis, which points, in the absence

of a better term, I shall call "*centres of conjugate foci.*" This term is perhaps as good as can well be devised, but still (although not wishing to be fastidious about a name) it does not quite please me, as the word "centre" seems to imply, and may serve in some cases to perpetuate, a general and very erroneous impression, viz., that something like a convergence of rays or a meeting of focal points there takes place — something in short which renders the place of this centre (or rather the places of these centres) the best for placing limiting diaphragms, &c. As we proceed it will appear what does take place at such points.

Every possible case of conjugate foci is evidently included within two extremes (inclusive), one extreme being that where the lens or compound is directed to parallel rays, the other that where it is used in forming equal conjugate foci; and secondly, the same range of foci, the lens being reversed in position. Where the compound lens is strictly symmetric there will be, of course, no difference on its reversal. Beginning with the simplest case, viz., that of a symmetric compound, applied to form equal conjugate foci, as in figure or case A, where the lenses *l l'*, and the outer conjugates *C C''* being each equal, any centre belonging to the combination, *so used*, must, of necessity, coincide with the centre of construction.

A



A 24 24 P=12

There is a special point connected with this precise case worthy of observation, viz., the distance between the lenses may be *any quantity or nothing* without affecting the power (or equivalent focus) of the combination; in other words, the power is here always equivalent to that of a single lens of the combined power of the lenses *l l'*, or, assuming these to be each of twenty-four inches focus, then the power of the compound will be —

$$(A)\quad \frac{1}{P} = \left(\frac{1}{24} + \frac{1}{24}\right) = \frac{1}{12} \text{ or 12 inches.}$$

This absence of effect, while separating the lenses more or less, is due to the rays passing parallel through the intermediate space. As a general rule, wherever the rays pass through a compound parallel to the axis of same (whether it be through a lens or a space between two lenses), no effect is produced by making that thickness or space more or less, while, on the other hand, wherever the rays do *not* pass parallel to the axis, whether this be through glass or air, or any other medium, the compound *is* affected by the thickness of the same.

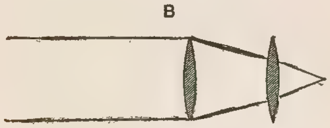
To prove this, suppose the compound represented in fig. 1 be applied to parallel rays, and assume the distance (or d) between the lenses to be twelve inches. The power of the combination will now be —

$$\frac{1}{P} = \frac{1}{f} + \left(\frac{1}{f} \times \frac{f-d}{f}\right)$$

$$(B)\qquad = \frac{1}{24} + \left(\frac{1}{24} \times \frac{12}{24}\right)$$

$$= \frac{1}{16} \text{ or 16 inches the equivalent focus.}$$

B



B 24 24 P=16

We therefore see that the equivalent power of an open combination varies with the conjugates which it is caused to form, being least when applied to parallel rays (the lenses being assumed of the convex kind). We may also find that the "centre of conjugate foci" is, in the case of parallel rays, no longer in the centre of the combination, but removed towards the first lens. In the case before us (*B*) it will have moved two inches. The theoretic proof of this change will be best deferred to another period of our inquiry.

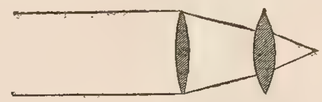
These two first cases being conducted with a symmetric compound, no variation, of course, would occur in reversal of the compound. Let us now examine the changes which take place in the equivalent power of an unsymmetric compound under varying circumstances.

C

C 12 24 P=12

C. The lenses here are assumed to be of twelve and twenty-four inches focus — the distance between remaining as in last case, viz., twelve inches—the shorter lens focus being turned to parallel rays— f and d being in this ease equal, the quantity represented by $\frac{f-d}{f}$ in the formula given at case *B*, is — nothing — therefore the power of the combination is simply that of the first lens, or twelve inches.

D



D 24 12 P=12

D. This is the same combination of case *C*, but reversed in position, and the equivalent focus will be found by the formula of case *B*.

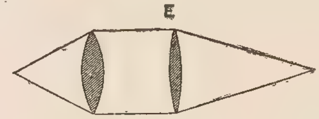
$$\frac{1}{P} = \frac{1}{24} + \left(\frac{1}{12} \times \frac{1}{2}\right)$$

$$= \frac{1}{24} + \frac{1}{24}$$

$$= \frac{1}{12}$$

The power of the combination is therefore the same as in the previous position, it is therefore not affected by reversal *when applied to parallel rays.*

E



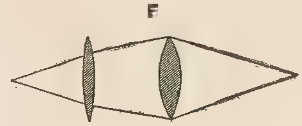
E 12 24 P=8

E. Here the same combination is applied to form *unequal* conjugate foci, the lens of shorter focus being placed at its own focus from the object. In this case the rays evidently pass parallel between the lenses, and therefore (as in case *A*) the equivalent power of the combination is unaffected by the distance of the lenses, — the power being simply the sum of the power of the two lenses, or

$$\frac{1}{P} = \frac{1}{12} + \frac{1}{24}$$

$$\frac{1}{8} \quad \text{or 8 inches,}$$

F



F 24 12 P=10·5

F. The combination of the previous case *reversed:* the lens of longer focus being now turned to the object, and placed at twelve inches from same.

We have now come to a case where in no portion of the distance do the rays pass in parallel lines, and where the calculations consequently lose their previous simplicity. For the present it will be sufficient to state simply the result, viz., that the equivalent power proves to be 10·5 inches, or nearly one-third longer in focus than in the previous position of the compound.

It is to be understood that the usual practice in conducting general investigations such as the present, viz., of neglecting the thickness of the lenses, is followed. It may also be observed that the focal lengths assumed for the lenses in the diagrams do not correspond with those in ordinary practice: neither of these, however, affect, except in quantity, the general results. Assisted by a reference to these diagrams, I expect to be able in my next communication to give a clear exposition of the nature of the centres of conjugate foci in open compounds: meantime, a comparison of the several diagrams may serve to show that with every variation of distance, &c., we so alter the conditions of such compounds that a thorough knowledge of the theory of these, combined with the most scrupulous care, is required in all cases (excepting that of comparative trials of compounds of equal calibre and similar construction) to ensure that the conclusions arrived at are anything better than worthless.

HINTS CONNECTED WITH THE DRY PROCESSES.

By George Shadbolt.

[Read before the Birmingham Photographic Society, January 31st, 1860.]

In compliance with a request made by the Council of your Society, "that I would contribute some paper on a subject connected with photography," to be read this evening at your meeting, I have decided on offering some remarks upon sundry manipulations connected with the various dry processes upon glass, partly because one of your most distinguished members, Dr. Hill Norris, was amongst the pioneers in ascertaining some of the principles upon which the successful working of them depends, and partly in the hope that I may induce a discussion upon the subject, being convinced that as a rule some of the most valuable suggestions have arisen in consequence of such a course of proceeding.

If I remember rightly, one of the earliest, if not the first, intimation given of the successful application of dry collodion was in a communication from Dr. Norris, published in the *Journal of the Photographic Society*, to the effect that he found a collodionised sensitised plate, when simply washed and dried, capable of receiving a developable impression in the camera. This did not excite much notice at the time, and it was not until twelve months or more afterwards that it appeared to be in any way recognised. The reason of such neglect I take to be in consequence of the general want of knowledge of *principles* so prevalent amongst the mass of photographers, and hence it appears to me of the utmost importance in detailing any formula to insist especially upon the principles involved in the operation. The conviction of the fact, that by far the majority of skilful operators content themselves with merely following out to the *letter* the instructions laid down for any particular process (just as they would follow the recipe in a cookery book for making a pudding), often to the total disregard of the spirit, was prominently brought under my notice upon an occasion when I wished to develop an impression which I had taken in very cold weather, upon a plate prepared by Dr. Norris's formula at the factory in Birmingham. The operation was performed at the house of a photographic friend, and in his presence, he being an able manipulator, and I was struck by his not only expressing surprise at my course of proceeding, but subsequently, on the arrival of another good photographer, mentioning to him what I had done as something quite new to them both. I have already stated that the weather was *cold*, and I may add that the plate had been exposed during the failing light of the afternoon of a winter's day: I consequently followed up with my dry plate the manipulation which experience had taught me, when working with moist collodion under similar circumstances, was most likely to give me the greatest amount of detail in the shadows, viz., to commence developing with a solution of a salt of iron, and subsequently to intensify the image thus revealed, by means of pyrogallic acid. I accordingly proceeded to moisten the surface of the plate, in the first place, by immersing it in a dish of distilled water for an instant; I then poured over the plate a small quantity of solution of nitrate of silver (about two grains to each ounce of fluid), and after draining away the superfluous liquid, I covered the plate with a solution of proto-sulphate of iron and acetic acid. As soon as the image appeared the plate was washed, the iodide of silver dissolved out with cyanide of potassium in solution, again washed, and then intensified by means of the ordinary one grain pyrogallic acid developing solution acidified with acetic acid, to which of course a few drops of nitrate of silver had been added. The plate was finally well washed and dried.

Now the part that excited my friend's surprise was, the use of a weak solution of nitrate of silver previously to applying the iron developer—for, strange to say, although they had been in the habit of developing dry plates with gallic acid, to which some silver solution had been added, it never occurred to them, that without the previous use of the silver there was nothing on the plate with which to form the image, and if it were added to the iron solution it became reduced immediately in the form of a fine powder before it could be got on to the plate. This explained to them why they had not been able to succeed in developing a dry plate with an iron solution, and it was consequently plain that they did not comprehend the particular part performed by the nitrate of silver in the formula with the gallic acid.

I may here remark, that I have subsequently employed with advantage for developing similar plates the following method, viz.:— Immerse the plate for a moment in *distilled* water, then cover it with a sufficiency of developing solution made thus:—Place in a Wedgwood mortar fifteen grains of proto-sulphate of iron and one grain of citric acid; reduce to a fine powder, and dissolve in one ounce of *distilled* water. *Just before using*, add two, or three drops of a solution of nitrate of silver (not from the sensitising bath), and this will remain for about the space of a minute without becoming discoloured, quite long enough to cover the plate and bring out the impression. Wash, clear, again wash, and then intensify with pyrogallic or gallic acid solution and a little nitrate of silver. I am not sure whether the gallic acid is not the better of the two, as with it there is no need to add any free vegetable acid, as is requisite with the pyrogallic acid. Of course, the plate must be finally well washed.

I have tried the above method with collodio-albumen plates under various modifications, but hitherto with only partial success: that is to say, I always got an image very full of detail, but it has been invariably contaminated somewhat in the deepest shadows, as if the plate were very much over-exposed. I am therefore hopeful that, by further experiments, we may in this direction find the solution of the problem of readily producing on dry plates an image with a minimum of exposure.

I have heard it asserted, but with what foundation I know not, that if plates prepared by Dr. Norris's formula (which must be too well known to your members to need recapitulation) be exposed and not developed within some moderate space of time afterwards (possibly some days or even weeks), that the impression gradually fades out, and becomes incapable of development. This is a point upon which I trust that Dr. Norris may be induced to give his experience. There is one curious fact which bears upon it that I think worth naming here. Having at the early part of last year to take a journey to Scotland at a very short notice, and not having time to prepare any dry plates for myself, I procured a dozen from the Dry Collodion Plate Company in your town to take with me, as I could not rest contented to go to the northern section of our island without my camera, although the period of the year—mid-winter—was one very unfavourable to the photographer's operations. You are all probably familiar with the manner in which these plates are packed for carriage, with a small piece of cartridge paper folded into plaits so as to separate by a slight interval each plate from its neighbour. Now the curious point to which I allude is that where the paper came in contact with the sensitised film—although no visible difference could be perceived in that part—on developing the exposed plate, *no impression whatever appeared to have been made*. This was observable not only in a single instance, but in every one of the dozen plates which I took with me; and I have noticed the same thing in negatives taken by other photographers upon these plates. Why had the contact of a piece of fair paper removed all sensitiveness?

At the last meeting of the Photographic Society (London), a very interesting paper by Mr. Hardwich was read, and which may be found at length in the last number of The British Journal of Photography, upon the nature of the collodion adapted for the dry processes, in which he shows that collodion which has undergone partial decomposition acts in a similar manner with reference to nitrate of silver, as an *organic* substance. In this view I am inclined to think he is correct; for I well remember, that in corresponding with Dr. Norris, when he was perfecting the details of his process he mentioned the preference he gave to collodion that had become *rotten* from having been long kept, though he attributed the advantage to another cause, viz., its more ready permeability to the gelatine solution which he employed. In spite of the many failures which occurred to me in testing Dr. Norris's process at the time, I was never for a moment shaken in my belief of its excellence, because I looked at the *principle* involved, and was convinced of its general correctness. I imagined that my failures arose from some error in manipulation when removing the

free nitrate of silver before covering the plates with the gelatine solution; and wishing upon a certain occasion to prepare plates for picture-taking (not for experiment), I adopted the method of covering my plates with honey syrup after their removal from the nitrate bath, and previously to washing them. This I did principally with the view of ascertaining to my own satisfaction when my plates were sufficiently freed from the superfluous nitrate of silver, which I judged to be the case, when, after washing and draining the plate, on letting the last drop of liquid fall on the tongue, I could detect no taste either that was metallic or sweet. When this was the case I then immediately applied the coating of gelatine, which I used quite hot. Plates thus prepared developed evenly and without any stains. I found, however, that the character of the collodion made a very material difference in the facility of manipulation, so far as development was concerned; for if it were of the contractile kind, unless the image was perfectly brought out in a short space of time, the film rose under the action of the free acid in the developer in numerous minute papillæ, as it were.

By the use of the honey as above described it is also evident that I was employing the aid of the compound of silver with organic matter; and though this quite accords with the principle involved in Taupenot's process, as also in those of Barnes, Fothergill, and others, yet it is contrary to the theory propounded by Dr. Norris, who, unless I am mistaken, advocates the total removal of the soluble salt of silver prior to the addition of the organic preservative agent.

When discussing this point at a meeting of the North London Photographic Association, some time ago, between those capable of entering into the theory of the question, it was the all but unanimous opinion that the presence of some other compound of silver *besides the iodide* appeared necessary to the reception of an actinic impression; and this opinion is supported by the interesting fact noticed by Mr. Young, of Manchester, relative to the possibility of developing an impression *after* dissolving out the iodide of silver, provided that albumen or some other organic body were present, but not otherwise. It is probable that, as shown by Mr. Hardwich, the decomposed pyroxyline acting as a substitute for an organic substance, the apparent discrepancy may be reconciled. It is a point well worthy of being further experimentally examined.

There is another direction, slightly diverging from that last considered, in which there is a very promising field open for investigation. If we coat a glass plate with a very thin film of albumen, say white of egg one part, water seven parts, and dry rapidly by heat, coat with iodised collodion, sensitise, wash, dry, expose, develop, fix, and wash, we obtain an image which remains on the *albumen* even after removing the collodion film. Now such a process appears to me to entail a minimum of labour in preparing the plates, and avoids blistering, that bugbear of the dry processes. I have verified satisfactorily the feasibility of this plan, but there are many points of practice yet to be worked out. The horny kind of collodion when dried is very impenetrable to the ordinary developing solution; it is therefore highly probable that the powdery kind might replace it with advantage. Again, the admixture of alcohol to some considerable extent with the developing solution might materially assist in enabling it to penetrate the film, and it would also have the advantage of rendering the collodion film very easily removable as soon as the development shall have been completed. If the impression be obtained with plenty of detail I imagine that it is of little consequence about its being faint, as the intensification would, on albumen, be a matter of very little trouble and no difficulty after removing the collodion.

I think it more than probable that with a very short exposure, and by employing the ferric developer previously mentioned, some considerable advantages might be attained; but it must be remembered that I only give the *principles* to be acted upon, not having had the time to work out the details for ascertaining the easiest *modus operandi*, and it is rather in hopes that I may enlist some fellow workers in this direction that I am now induced to allude to the subject.

With regard to the relative capabilities of wet and dry collodion, I am entirely of opinion that the latter is quite equal to the former in its quality of rendering every gradation or half-tone. In one point alone does the former excel, that is in its rapidity of receiving an impression; but I see no reason why that inferiority in this respect with dry collodion should not, by perseverance, be overcome. I noticed that Mr. Hardwich mentioned a fact, to which Mr. Hughes assented, and which my own experience strongly confirms, viz., that the presence of bromide of silver in the dry film is a very important adjunct.

In the preceding desultory remarks my object has been, not so much to communicate any special novelty, as to apply a stimulus to the store of energy possessed by so many of my photographic brethren who are so fortunate as to have much more time than myself for useful experiment directed towards a certain point, and to indicate a field of operation in which I am convinced that laurels are to be won.

REPORT OF THE COLLODION COMMITTEE.

In March, 1859, the Photographic Society appointed a committee to examine samples of photographic collodion, and report upon them, with a view of arriving at a definite formula. Advertisements were issued, which were replied to by Messrs. Hardwich, Mayall, and Sutton; but the two latter of these gentlemen did not send in collodion in sufficient quantity to admit of its being thoroughly tested. Hence, although individual members have worked with the collodions of Mr. Mayall and Mr. Sutton, the committee in its collective capacity can only pronounce upon that prepared for them by Mr. Hardwich. They trust, however, that the investigation which they have undertaken will not be suffered to end with one report, but that other makers of collodion will come forward and assist the society in the determination of this difficult but important question.

In proposing to themselves a scheme for the general conduct of their operations, your committee did not think it advisable to place too much reliance upon experiments made in concert, since these must necessarily have been few and imperfect. It appeared to them better to allow the members to work separately, and afterwards to collect and compare their individual reports. Nearly a year has now elapsed since the committee was formed, and it cannot therefore be objected that its conclusions have been hastily drawn; neither can it be said that the report has been made without a full and impartial examination, for the names of no less than twelve members are appended, who are known to the society to practise every branch of the art. Portraiture, both in the studio and in the open air, landscape scenery, architecture, copying, and sculpture, have all been represented in this investigation, and the lenses employed, and plates covered, have been of every conceivable size. Further, as the various members of the committee differ in their views of the best modes of iodising photographic collodion, opportunity has been afforded of comparing the results obtained by each method, and of drawing conclusions therefrom.

This report, professing to deal with the practical working of negative collodion, may be naturally divided into two parts, for the experience of members of the committee using simple iodides does not admit of comparison with that of others employing in preference iodide and bromide conjoined. There is, however, one ground common to both, viz., the *mechanical properties* of the collodion under examination, and of these we proceed to speak.

The committee are unanimous in thinking that the collodion which Mr. Hardwich has sent in to them is comparatively if not entirely free from glutinosity, crapy lines, contractility, and other defects of the film, which were very commonly met with some years back, when the manufacture of collodion was first commenced. The reports of Messrs. Delamotte and Fenton are the most valuable on this head, since they have worked on glasses of a large size, viz., twenty-four inches by eighteen, and eighteen by fifteen. Their experience is, that although the collodion sometimes contains too much soluble cotton for these large plates, and occasionally requires thinning down with ether and alcohol in very hot weather, yet that the pyroxyline is nearly of the right kind as regards flowing properties, and may with justice be said to be well calculated to support a smooth and even layer of iodide, without any woolliness or ridges.

Another matter which falls under this same head of mechanical properties is the tenacity of the film, and its adhesion to the glass. We are satisfied that the collodion submitted to us is sufficiently tough to bear a reasonable application of water, either from a tap or a jug, without tearing, and that with ordinary care in manipulating it will not fall away from the glass. No member of the committee, as far as can be gathered from their separate reports, has been compelled to grind the surface of the glass at the edge to prevent splitting, or curling off on drying. Mr. Fenton, indeed, states that on using some of the earlier samples of collodion supplied to him by Mr. Hardwich, he was obliged to roughen his largest plates, but that with the collodion which he received during the past summer and autumn he did not find it necessary to take this precaution.

The report being satisfactory on the points above mentioned, we next consider the quality of the film yielded by the collodion, as regards closeness or openness of texture, and here it is found that some members speak of it as being too horny. That the film does possess such a structure is certain, and hence the question of how far this must be considered a defect. The following are extracts from the reports of those members who make complaint. Mr. Bedford says—"One fault I have found is a too quick drying of the film in hot weather. If, as is frequently the case, the plate has to be kept over fifteen minutes or so, it is necessary to add alcohol to the developer to prevent stains and patches of unequal development." Mr. Hughes also observes—"My dark room being small, and w t a southern exposure, becomes almost like an oven in hot

weather, and one of the principal difficulties which I encountered was the partial drying of the film whilst it was in the camera slide." The attention of the other members of the committee was particularly directed towards this horny quality of the film, but, with the exception of Mr. Morgan, who speaks of it as inconvenient but not insuperable, they make no allusion to it in their replies.

Passing next to the consideration of the photographic properties of the collodion, we find it necessary, as before said, to distinguish between the results obtained by simple iodides and those from iodide and bromide in mixture. To begin with the former, there are embodied in this report the observations of nine or ten members who have worked either with iodide of potassium as an iodiser, or with iodide of cadmium. The following is an epitome of their conclusions:—

First, with regard to the sensitiveness of the collodion, the opinion of the majority is, that it is unsurpassed. Mr. Delamotte, who has worked in the subdued light of the Crystal Palace, at Sydenham, with lenses of very considerable focal length, speaks confidently on this point; and Messrs. Bedford, Hughes, Robinson, Sedgfield, and Williams, are of the same opinion. Mr. Frith also, in a letter dated Cairo, August 1st, 1859, says—"I find this collodion exceedingly rapid. Three days after iodising (potassium iodising solution), it will take a picture with the smallest aperture of the landscape lens (fifteen-inch focus) in five seconds; and I have some hope of getting an interesting series of instantaneous pictures, by using a stop of 1½ inch diameter on the portrait lens (3¼ inch diameter). The lens then covers a 4¼ inch plate, with tolerable depth of focus, and I can obtain a sufficiently-developed picture with an absolutely instantaneous exposure, sailing boats with the ropes sharp, moving figures, &c." Under date of the 7th of August, he adds—"We have just returned after having spent five days in the mud-house of an artist at the Pyramids, where we were devoured by thousands of sand-flies; the water very bad, and the heat great. I worked hard, and took some fine pictures. Nothing can be more satisfactory than the performance of the collodion. I still get landscapes with the smallest aperture of the view-lens in four seconds, and have taken capital pictures in the heat of the day. I should imagine the temperature in my little tent could not be less than 130° F. The developing solution was quite hot.*

Mr. J. Morgan, of Bristol, in the report which he has forwarded, does not coincide with the above statement, for he says—"I am able to obtain a similar negative with another collodion in one-half of the time." This discrepancy is the more remarkable because the nitrate bath in each case was made out of pure nitrate of silver crystallised purposely for the committee. The developer, however, which Mr. Morgan employs contains less than the usual proportion of pyrogallic acid, and he sometimes, but not invariably, adds a small portion of citric acid.

When iodide of potassium is employed as the iodiser, the collodion loses its sensitiveness very considerably after a time, but the members of the committee are not agreed as to how long it will keep in good working condition. Mr. Bedford says—"I prefer using it newly iodised, say in about two days: after five or six days it loses sensitiveness, and deteriorates rapidly; but in this state it works well enough when time of exposure is no object. I kept it in even working order by adding some freshly iodised collodion to the stock-bottle daily." Mr. Delamotte writes—"I found, whilst working in the Crystal Palace, that it lost a good deal of its sensitiveness in three or four days, and in offering a suggestion for the improvement of this collodion, I would say that, if possible, it be made to retain its sensitiveness longer, with the same qualities it now possesses in other respects." Mr. Morgan says, in reference to its keeping qualities—"A day or two after iodising is the best time. I have taken a landscape picture with it after a month, but I do not think it improves by keeping as long as that." Mr. Robinson reports—"It gives good results for portraits if used immediately after iodising, but I prefer it when it has been kept two or three days, or for landscapes two or three weeks." Mr. Sedgfield, giving his experience in stereoscopic photography, writes—"I cannot say much as to its keeping qualities, as I seldom have any by me more than a week old." Lastly, we have the report of Mr. T. R. Williams, who, working in a London studio, necessarily requires the maximum of sensitiveness. He considers that the collodion does not alter much during three or four days, but that afterwards it becomes useless for the purpose which he requires.—The foregoing observations apply to the summer season of the year, and not to the colder months, during which the deterioration in sensitiveness is less rapid. Mr. Williams has lately obtained good pictures after a fortnight's keeping.

We next examine the collodion with regard to the quality of the negative which it yields, and in this respect we are able to pronounce upon it favourably. The image is very sharply defined, and the development can be pushed to an extent sufficient to bring out the deepest shadows without adding too much to the opacity of the high lights. The printing qualities of the negative are good, and those parts of the film which are protected from light remain free from fogging. The liability to staining and marks of all kinds in hot weather is not great, as attested by Messrs. Delamotte, Morgan, and others, who state that the collodion gives a clean and bright picture.

In drawing up a report in which gradation of tone in a photograph is spoken of, it must always be borne in mind that the character of the light and the aperture of the lens have much to do with the hardness or softness of the picture; and this observation we find corroborated in the separate reports sent in to us, for, whilst one or two members have found at times a difficulty in obtaining sufficient contrast, others have complained of excess of intensity, although both were working with the same description of bath. Mr. Bedford alludes to this, and says: "In a strong light, or glare of sunshine, there is, I think, a tendency to too great density, a too rapid starting out of the image. This I have remedied by employing a weaker developer, and, in some cases, by washing the free nitrate away from the plate before putting it on, or washing the plate once or twice during the development, using, in that case, silver to give force to the image. By this means I avoided hardness, and secured a good picture under trying circumstances of light and heat." Allowing for these differences in intensity, which must occur with any collodion, we find that the preparation which we have examined is sufficiently good, and that it is not a collodion of that kind which requires a considerable addition of nitrate of silver to the developer, or fails to yield an intense picture unless acetate be added to the bath. As a rule, the image will attain its maximum density shortly after the pyrogallic acid is applied, and there will be a fair share of the characteristic drab or cream colour upon its surface.

Whilst speaking of gradation of tone, it may also be remarked that different developers have been employed by the committee to assist in securing the correct amount of contrast under varying conditions of light and temperature. Thus Mr. Delamotte, working in the Crystal Palace, at rather a low temperature, has developed plates of the stereoscopic size by preference with sulphate of iron; and Messrs. Robinson and T. R. Williams have occasionally used the same reducing agent for portraits. The intensity of the negative taken with sulphate of iron is often sufficient; but, if not so, the development is completed with pyrogallic acid and nitrate of silver.

One question put to the individual members of the committee was the following:—"Have you found the collodion to injure the bath by long use?" The reply is in the negative, and this we consider of importance, because we have on other occasions worked with collodions which had a decided effect in throwing the bath out of order. The committee, as a body, pronounces no opinion on the cause of this; but certain individual members attribute it to the employment of methylated spirits, in place of the pure ether and alcohol which are used by Mr. Hardwich.

The seventh question in the suggestions on the order to be observed in drawing up the reports was as follows:—"What do you consider the principal defects in the collodion?" Mr. Hughes complains of transparent spots with tails, taking the direction of the draining, and showing most distinctly when the collodion was newly iodised; by using bromo-iodide, instead of simple iodide, and developing with sulphate of iron, the spots almost invariably disappeared. Two or three of the members speak of narrow black lines like threads in the direction of the dip; these same lines being sometimes, but not invariably, remedied by rocking the plate laterally immediately after putting it into the bath.

Under the head of Question 9, viz., "State anything which has occurred to you in the course of your experiments likely to forward this investigation," we have the following suggestions from Mr. Russell Sedgfield:—"A collodion iodised with *cadmium* only is very useful in extreme cases, such as dark glens, &c., and I always carry a little with me on my excursions. At present my decision is in favour of a pure potassium iodiser, with some cadmium collodion carried separately for use on occasion, either by itself or, perhaps preferably, mixed. The mixture of the two seems the best for the majority of amateurs, who cannot be expected to go into detail in these matters, and whose consumption is small and irregular. When iodised it certainly keeps much better than it would with potassium alone, and I have just been taking, to satisfy myself, some excellent portraits and views with remnants from my last journey, iodised three months ago." This plan of mixing together collodions possessing opposite properties has been successfully adopted by several members of the committee, when they have satisfied themselves as to the working qualities of each collodion by using them apart.

Mr. T. R. Williams was supplied with cadmium collodion from the committee, in addition to the same plain collodion iodised with potassium; he remarks upon it as follows:—"I have found the cadmium collodion to give the softer image of the two; but they are both good, and some of my best portraits have been taken with them. By using sometimes pyrogallic acid, and sometimes sulphate of iron, and occasionally both on the same plate, it is possible to obtain either a soft, delicate effect, or a bold and hard picture. The cadmium collodion does not appear to deteriorate by keeping in the iodised state."

Included under this same head of "Suggestions for Improvement," &c., we give the following, also from the pen of Mr. Sedgfield:—"Lately when taking interiors I have adopted a suggestion of Mr. Sutton's, by adding strong alcohol and soluble cotton, with a little more iodide, to the samples of collodion which I have by me, in order to get a pappy film capable of retaining its moisture longer than the ethereal and skinny mixtures. My experience of this kind of work has been so far satisfactory, that next season I shall carry the plan out more regularly, although I cannot say whether such a collodion is equally suited for use on all occasions."

Having now concluded the first division of our report, viz., that which refers to the collodion prepared with simple iodides, we pass on to the

* It is only fair to state that the above favourable opinion from Mr. Frith was extracted from private letters written without any idea that they would be included in this report.

second, in which is given the experience of those members of the committee who have worked with iodide and bromide combined.

Mr. Fenton has used collodion sent to him from the committee, in the regular course of his photographic practice during the past year, and has been at some pains to ascertain in what manner it ought to be iodised in order to secure the best results. His lenses have been almost entirely single ones, and of every variety of focus; the character of work, landscape and architecture, with occasionally interiors, and copies of drawings and sculpture. His experience is as follows:—"The collodion prepared with iodide of potassium only ought not to be entirely rejected; it is useful on occasion, being sufficiently sensitive, and producing, for some purposes, a good quality of picture. It has, however, formidable drawbacks, such as soon becoming red and insensitive, and being liable to show white spots, often when used alone, but still more frequently when added to any other collodion." On the whole he gives preference to a mixture of iodide and bromide, which not only produces a far more stable collodion, but represents the colours of landscape scenery in a truer gradation, and brings out the sky and the foreground of the picture at the same time, without solarising.

With reference to the salts which should be employed, Mr. Fenton has worked with a collodion prepared by Mr. Mayall, containing iodide and bromide of magnesium, and also with one made by Mr. Hardwich with the same compounds. The two collodions, however, did not agree in properties, for whereas the former was rather glutinous, and gave a fair share of intensity, the latter was limpid, and produced a weak negative. By mixing them together a good working collodion was obtained, with which some of the views of Oxford now in the Exhibition were taken. He is not inclined, however, to recommend the use of the iodide and bromide of magnesium.

During the months of August and September Mr. Fenton worked with plain collodion similar to that sent to the other members of the Committee, but iodised with iodide and bromide of ammonium and cadmium dissolved in the usual proportion of alcohol. It is extremely sensitive, and takes the dark parts of the picture well, but should be kept for some days after iodising, or there will be occasional white spots and lines on the image. This collodion improves by keeping even for many weeks, and is so far good, but it is difficult to use it for landscape work in hot weather, because the least over-exposure destroys the intensity, and makes the picture flat and thin. A solution of sulphate of iron was used to develop, with mixed pyrogallic acid and nitrate of silver as an intensifier.

Mr. Hughes is an advocate for the employment of iodide and bromide conjointly in portrait collodion, and the reasons which he alleges are these:—"Although with simple iodide a picture of superlative excellence may be taken by a skilful operator, yet to the amateur who desires only a good average result, with little liability to failures, bromide is an assistance. I would direct the attention of the committee to this point."

Mr. J. Spencer communicates an account of some experiments which he has made during the preceding season with bromo-iodised collodion sent to him from the committee. It appeared to him to be very valuable for some kinds of landscape work, and at the season of the year when the light is strong. In the winter, however, he works by preference with a simply iodised collodion, containing only iodide of cadmium. As regards the proper developer to employ with bromo-iodised collodion, he commenced his experiments with sulphate of iron, but as the heat became greater he found pyrogallic acid to be sufficient.

In order to render the above observations complete, we require exact experiments on the comparative sensitiveness of the simply iodised and bromo-iodised collodion. These have not at present been made, and so far the report is incomplete. Without doubt, however, the latter retains its properties very much longer after iodising, and has the merit of producing delicate half tones, whilst a sufficient intensity can in most instances be obtained by carrying on the developing action with pyrogallic acid and nitrate of silver.

Mr. Thurston Thompson, a member of the committee, works exclusively with the bromo-iodide. All the pictures which he has exhibited were taken with a collodion of his own manufacture, and he was unable during the last season to give such careful attention to the collodion sent to him as would justify him in speaking confidently of its merits.

The names of other gentlemen, members of the committee, viz. Mr. Llewelyn, Mr. Maskelyne, Mr. Mayall, Count de Montizon, Mr. Spiller, and Mr. White, will not appear in this report for the same reason.

Mr. Malone, on whom devolved the task of examining the formulæ as regards their chemical aspect, has expressed his full satisfaction with that by which the collodion sent to the committee by Mr. Hardwich was prepared. He has assisted at the manufacture of the pyroxyline and collodion, not in small quantities but on a commercial scale, and has received a complete list of details and precautions which are necessary in order to ensure success.

In concluding this report the committee have much pleasure in expressing their opinion of the superior excellence of the collodion submitted to them by Mr. Hardwich, and they can confidently recommend the society to stamp the same with the full mark of its approbation.

NOTICES OF RECENTLY PUBLISHED STEREOGRAPHS.

The Gibbous Moon.—Samuel Fry, *Brighton*.—It has been observed that the first ocular demonstration of the globular form of our satellite was presented to us by means of the stereoscope. In our last volume we noticed the publication by Mr. Fry of a stereoscopic illustration of the Full Moon: he has more recently produced one in the phase known as gibbous. The negatives from which the two pictures are printed were taken at an interval of eleven months apart, and the variation in points of view is equivalent to an angle of 6¼°. The left hand picture was taken at the Hove Observatory (belonging to Mr. Howell), at the latter part of November, 1858, and the right hand one not till the middle of October of last year. The moon's age, as represented in the stereograph before us, is about sixty hours after the full, and owing to the obliquity of illumination many very beautiful volcanic craters and cones on the gibbous edge are rendered visible, the shadows produced by the irregularities of the surface tending materially to enhance the brilliancy of the effect.

Owing to the satellite being in Apogee when one of the negatives was obtained, and in Perigee when the other was taken, the respective sizes of the corresponding pair were materially different, just as would happen in fact if an operator were to take a portrait of a sitter for one picture when located at the extremity of his glass room, and the other when he had moved a third of the distance nearer to the lens: it will therefore be readily understood that it is requisite to resort to some ingenuity in order to print from them so as to make them combine harmoniously together. We have no doubt that the present one will be even more popular than the former publication.

We understand that Mr. Fry is still indefatigably pursuing his astro-photographic labours, and that we may hope ere long to be introduced to some other magnates of the stellar circle.

Dr. Paterson's Dry Collodion Process.—In our notice of the proceedings of the Photographic Society of Scotland the doctor's *preservative* agent was unfortunately omitted by our reporter. It consists of a solution of gum arabic in water, the strength being such as merely to allow of its being passed through filtering paper. [Query—Was not this "process" patented by Dr. Hill Norris some few years ago?] It is only fair to Dr. Paterson to say that he made no claim to novelty in his communication, although in the official notice sent to the members of the society it was characterised as a "new" process.

NOTES OF A PHOTOGRAPHIC TOUR IN THE HOLY LAND.

No. XIII.

The next morning the sun broke in the east with all the signs of a storm; the sun came up upon the hills of Lebanon with a red glow, and the clouds that lay in the east were of the same tint; so that John, when he came out of the tent, quoted the words of the Saviour, and said, "We shall now know if the weather signs are the same in Holy Land as they were two thousand years ago, for the morning is *red and lowering*."

We were in the saddle early, and rode off before the men had struck the tents. Following down the sea shore we soon came to a small village, known as Sarfend, which is the ancient Sarepta, or Zarephath. You recollect it—what child is there in Christian lands that does not recollect it?—as the place of that wonderful barrel of meal and cruse of oil which the prophet gave to the widow woman, whom he found at the gate gathering sticks. There is an exquisite beauty in that story of the woman and her child, which impressed me in boyhood perhaps more than any other of all those Bible stories in which children so much delight. Hence the peculiar pleasure with which I rode over the hill, and looking at the modern village, recalled the scene when the prophet asked of her water to drink, and she went and fetched it.

We did not pause here longer than was necessary to enable me to take a view. Other places of interest were before us, and we wished to have all the afternoon at Cana, if, perchance, we could find any place that would fully satisfy our notions of the locality of that city of the first miracle. We accordingly put our horses to their best speed where the road would allow it, and hastened to the southward by the same road we had gone the previous day with our friends. Long before noon a driving storm commenced, and we repented our fondness for society that had gotten us into

this dull ride, retracing our steps in the face of a tempest. You will observe that our trip to Beyrout rendered necessary a return all the way to Acre, or nearly there, before we should be able to turn off to the eastward towards Nazareth and Cana.

But we pressed on; and, in spite of the rain and wind and cold, we did resist the temptation to pause at Tyre, and actually reached Acre that afternoon; but here we incontinently gave up our plan, and dashed into the city. Never was shelter more welcome. We found such lodgings as we had had in Tyre, and slept soundly in spite of myriads of fleas.

In the morning I awoke, and found the weather clear and fine. John was sleeping soundly, but I roused him with a bucket of water. Capital places these oriental huts, where nothing is harmed by dashing a pail of water over a drowsy friend in bed. His bed was the corner of the room, its furniture nothing; mine had been as soft and warm,—the next square to John. He sprang to his feet, shook himself, and was awake — in fine humour; thankful for the bath, which we improved on by a plunge in the surf of the Mediterranean, and then we set off in search of our people.

Perhaps you would like to know what a night's lodging cost us in Acre — Akka, as they call it; Ptolemais of old fame. It cost three piastres, that is, eight-pence each, including a chicken and coffee in the evening, and two chickens and two coffees in the morning, and this we were obliged to force on our host, who was a Mussulman, and had taken us in from pure compassion. You will say that we might have paid him more liberally. So we might, but that it was necessary to offer no more than the market price, that our account might be square. We paid him what was customary, and he could not reproach us with using his hospitality and overpowering his merit by a large payment. Nevertheless, when we were mounted in our saddles again, John dropped into the hand of our host a piece of silver "for the poor," which — let us be charitable — probably went to the benefit of at least one poor wretch I could name in Akka.

It was high noon when we rode over the hills that commanded a view of Cana, the city of the miracle, now a deserted village. There was nothing whatever here to interest us, except the history which gave such sublime character to the hills and plain around the white houses of the little hamlet. All Syrian villages are alike:— a mass of low houses, usually built rudely of the white lime-stone of the country; the roofs are chiefly stone in the better houses, but in the poorer are brick and mud; the interiors are plastered walls and mud floors. Sometimes a partition of mud is built across, not rising to the roof; but usually the hut has but one room. Hence it is useless for me to describe to you the present appearance of these old places. They are all modern Syrian villages.

The tents were not at Cana. I enquired of the natives, but could learn nothing of Hassan and his people. So, turning our horses' heads, we crossed the country in the direction of Nazareth.

Two strangers travelling alone, and without guides and attendants, presented a tempting subject of robbery to the Ishmaelites of the hill country. Our intention to go to Nazareth was known while we were lingering and making enquiries about Cana, and three or four worthy inhabitants of the place laid a plan to intercept us.

We had scarcely advanced a mile on the way when we were met by a party suddenly riding down on us from a cross valley. Their intent, long before they reached us, was sufficiently manifest, and we drew up to meet them.

Some half-dozen times I have had encounters with these scoundrels of Syrians, and found them always alike, thorough cowards of the most cowardly sort.

As they came down on us we drew our revolvers, and covered them. The demonstration was sufficient. They pulled up suddenly, and paused in a mass to consider.

"Who are you?" they demanded.

"None of your business," was the cool reply.

"But it is our business. These are our lands. This is our country."

"This is God's land, and by the help of God we are passing through it; for he is the special protector of Englishmen."

"What do you wish?" they asked.

"Only that you go quietly by that road to Cana. If you go not, in three minutes the vengeance of Allah will descend upon you in the shape of bullets of lead. See, we carry the weapons of Satan"—and I showed them the barrels of a revolver pointed at their heads.

The leader fell from his horse to the ground at the sight, and crawled up to John's side, and began kissing his foot.

We ordered them home, and home they went, we taking care that they should not see our backs till they were on a hill out of the reach of bullets, and then we went like lightning over to Nazareth.

As we descended the ravine on the side of which Nazareth is situated, we caught sight of the tents of a party of travellers among the olive trees which are near the Fountain of the Virgin and the Greek Church. They shone white and pleasantly among the dark green foliage, and in a few moments we could see our own dingy canvas among them, and recognise our servants, who stood in front of the fountain. They did not shout as we approached. There was, on the contrary, a profound silence over every thing, which we had difficulty in explaining. We rode up at a gallop, calling out to Selim as we approached, to know if all was right.

All was right with our affairs; but the other tents proved to be those of our late fellow travellers, and the lady was lying very ill —they believed dying.

The intelligence was a shock. We had thought of meeting them again; but when we parted at Samaria we were all confident she was so much improved, that all apprehension of danger for her health and life were gone.

You may think it somewhat strange that our approach to Nazareth, the place of the youth of Christ, should have failed in producing sufficient impression on us even to keep in our minds the idea that it was Nazareth, when we heard this sad story of our fair companion. But there was something about that young girl—a gentleness, a purity, and withal a glow of enthusiasm, which had endeared her to both of us more than I can tell you. I had laughed hitherto at John's delicate attentions to her; but my honest friend, frank and generous in all his dealings, did not love the beautiful American girl any more sincerely than did I and every one else who met her in her sad pilgrimage.

We found her lying in the tent, on the low iron bedstead, pale, calm, and cheerful, but manifestly very weak, and very near that end of earthly pilgrim-walks to which we are all more or less rapidly travelling. She welcomed us with a cheerful "Good afternoon," and spoke with the utmost delight of the few days of pleasure she had had since we parted. From Samaria they had crossed the southern branch of the plain of Esdraelon, resting at various places, among which was one day at the tower of ancient Jezreel, and another at Nain, and yet another on the summit of Mount Tabor. "It was so glorious," she said, "on that hill top, to look around on Galilee, and down into the blue depths of the Lake of Gennesaret!"

We have been resting now one week at Nazareth. This is the eighth day, and she is to-day stronger and better. She has had changes — now for the better and now for the worse. Meantime we could not go and leave her or her friends. I shall have a busy time while we remain here. I have already marked out a dozen points of view of Nazareth and the surrounding country. Every spot is teeming with historical interest and natural beauty, and I long to set to work with my camera, for a rich harvest awaits me. But I sigh for collodion, wet or dry, "neat or preserved."

It is a long time since I saw a number of The Photographic Journal, and I look forward to the coming batch with as much interest as a school-boy for his plum-cake.

D. T.

Meetings of Societies.

ARCHITECTURAL PHOTOGRAPHIC ASSOCIATION.

The opening of the Exhibition of this Society, on the 8th instant, was inaugurated by a *conversazione* at the rooms, No. 9, Conduit Street. There was a full gathering of members and visitors, who appeared highly delighted with the entertainment provided for them.

The photographs hung around the gallery are well classified and arranged, so as to be displayed to the best advantage. The subjects are sufficiently varied and interesting, being drawn from the Holy Land, Turkey, the Roman States, and Rome itself, Northern Italy, Spain, France, and our own country. They are the productions of many of our most eminent photographers, including Messrs. Bedford, Bent, Clifford, Cundall, Cocke, Downes, Fenton, Greenish, Macpherson, Melhuish, Ponti, &c.

The chair was taken by Professor Cockerell, President of the Royal Institute of British Architects, who addressed the company, and introduced Professor Donaldson, who he said would explain and illustrate the photographic pictures forming the collection.

Photography the Instructor of the Architect; and Architecture the best Subject for the Photographer.

Professor DONALDSON, who was received with applause, first described his interview, in 1840, with M. Daguerre. He then proceeded to say, that photography, in relation to architecture, was one of the most important discoveries of the age, and extremely useful to architects, whether regarded as artists or men of science. The simplest building, devoid of meretricious ornament, lost nothing when made the subject of a photographic picture, while, at the same time, the most elaborate structures of Rome, mediæval monuments, &c., were depicted in all their elaborate details and correctness, light and shade. Each point had its due prominence, and all were harmoniously subjected to due relations with the whole. The rapidity with which photographs were taken was a very important consideration; for in foreign countries, where suspicion followed the footsteps of the lover of art, it was sometimes found necessary for him to abandon his task before he had succeeded in sketching his view. When travelling in Asia Minor, he had often diverged from the direct road to catch a glimpse of some important or interesting spot, and often been forced to depart without obtaining the views which he wished; whereas, with the apparatus photographers employed, it was possible in a short time to obtain a correct and vivid image of the desired object. Had photography been discovered two or three hundred years ago, what precious memorials should we not now have had of countries visited by Benjamin of Tudela and Marco Polo! What mementoes should we not have had of Asia Minor, and Greece, and other parts of the classical world!

The Professor then drew attention to the various photographs in the room, in the order in which they were classified and grouped. Commencing with Rome, he remarked that there were many associations connected with the word Rome of a religious and an artistic nature, and he almost shrunk from venturing upon a subject which seemed to rise so immeasurably high. Two of our countrymen, Messrs. Macpherson and Anderson, were among the principal photographers of Rome. The first-named artist had contributed several views in Italy and Rome to this Exhibition; amongst them was that scene of desolate, solemn grandeur, *The Roman Forum,* the scene of the renowned amusements and games, where eighty thousand persons could assemble within its ample walls to witness them—where hundreds of lions were brought into the arena to try their strength, and where numerous gladiators, and probably Christian martyrs also, fought and died. He would call especial attention to the views of the Colosseum at Rome, as combining gracefulness of effect and correctness of detail in a most harmonious whole. He also pointed out the views of the temple of Antoninous and Faustina, and the theatre of Marcellus, whose arches were now occupied as common dwellings, and one of the lower arches of which was used as that smith's shop so well known to all the art-students of Rome. Other Italian towns and cities were mentioned. Assisi with its temple of Minerva, and Narvi with the bridge of Augustus, which still remain to excite the admiration of art-students.

The combination of grace, harmony, and beauty in those Roman monuments revealed to the mind a new world of delight. He felt that he could not pass over this portion of his subject without bestowing an eulogium upon that wonderful artist, Peruzzi, whose thorough knowledge of perspective, whose vivid imagination, and whose skill in the combination of light and shade, gave him a peculiar power in grouping, and the result of which was a series of views which overpowered all criticism, and carried one away with enthusiasm.

Following the flight of the Roman eagle, the Professor next led his audience into Spain, and traced the influence of the Roman struggles with Carthage, in that country, upon the growth of art; as manifested in the numerous remains which were so beautifully depicted by Mr. Clifford in his photographic views. He alluded more especially to a view of the ruins of the Roman theatre at Merida, and a beautiful picture of the interior of a corridor of the Alhambra. Among the numerous other views, claiming particular attention, the Professor pointed out the Gothic architecture on the door of *Santa Maria del Mare,* and of the cathedral at Leon, as showing how specific minuteness was, in those pictures, blended with the grand and the sublime. More modern art is illustrated in the Puerta de Alcala at Madrid, and in the theatre and custom house at Barcelona. These were evidence of the art-feeling that still existed in Spain; although they were not so pure and lofty as those which existed in other capital cities of Europe. There was, however, much of art to be learned in that country. The Spaniards were a people of vivid imagination; and when they enjoyed the vast wealth drawn from America, they employed artists of the first reputation to ornament their religious and secular edifices, and paid them liberally. Their past works are full of suggestive hints to warm the imagination of artists from the colder regions of Northern Europe.

Passing on to Venice, the Professor gave a succinct history of the numerous works of art which are to be found in that renowned city, drawing a distinction between the classical and elevating features and those that were wild and voluptuous. He described the Venetian merchants, endowed with great taste, and liberal in their patronage of art, who devoted their time and money to the adornment of their public squares, churches, and public edifices. Much of this refinement in taste might be attributed to their intercourse with Byzantium, whence they derived many of their most striking monuments.

The views in Venice exhibited in the room were very numerous and beautiful. We might fancy ourselves walking in the midst of the façades, columns, monuments, and palaces of that city of the waters. The view of the *Palace of the Doge* was one of the most striking monuments of modern art.

The Professor observed that the photographic views in Venice are characterised not only by faithfulness, but by a certain richness and strength of outline peculiar to photography. In the course of his remarks he touched lightly upon many points of interest, historical and classical, connected with several of the views exhibited. Referring to cathedral architecture, he said there was nothing more wonderful than the boundless expenditure of the Christian church during the brief three centuries of the mediæval period. The erection of Gothic cathedrals was entirely a gratuitous work. We could not traverse the length and breadth of England without being struck with the number and beauty of the religious edifices erected within this period; and in France, Germany, and Spain, there were similar indications of that ardent spirit which resulted in the erection of cathedrals and churches of vast extent, rising many hundred feet towards heaven. The monks went from palace to palace, and from cottage to cottage, gathering from all classes of the people the means wherewith to build these edifices. The English cathedrals were illustrated by many views in the gallery. The civil and domestic architecture of the mediæval period was also illustrated by many striking views; and our own true, happy England, with its Gothic abbeys, churches, baronial halls, and colleges, were illustrated by many views in the gallery. In connection with these works he would mention the names of Mr. Fenton, Mr. Cocke, Messrs. Dolamore and Bullock, Mr. Robinson, and Mr. Bedford, the latter of whom was not only well known to the profession as a photographic artist, but was particularly successful in his combinations of building and landscape scenery—views remarkably clear and distinct in all their various tones.

The Professor concluded his remarks by saying that his object had been to offer a few brief passing suggestions to guide the inquiries of others; to show how fine a subject architecture was for photographers, and how, in return, photography might become a teacher of the architect.

The discourse, which we have but briefly sketched, was listened to with great attention and interest, and the Professor, upon resuming his seat, was greeted with much applause.

The CHAIRMAN then rose and said that he was quite sure he should be commissioned by the meeting to offer to Professor Donaldson their most sincere thanks for his admirable paper, to which he had listened with the greatest interest, and which was worthy of the highest admiration.

The resolution was passed; and, on the motion of Mr. MAIR, a vote of thanks was unanimously accorded to the Chairman.

LONDON PHOTOGRAPHIC SOCIETY.

THE Anniversary Meeting of the above society was held on Tuesday, the 7th instant. The President, LORD CHIEF BARON POLLOCK, occupied the chair.

The attendance of members was smaller than usual.

The minutes of the last meeting were read and confirmed.

The CHAIRMAN: Gentlemen, I have to congratulate you upon our assembling at the commencement of another year of our Photographic Society.

The first thing that I have to notice is, that I believe this is the last time that we shall assemble in this room upon the occasion of an anniversary. We have given notice that we quit these premises next midsummer, and I hope the general body of the society, when they learn that we pay £300 a year for these premises for accommodation which we formerly obtained for £50 a year, will think that we have acted a very wise and prudent part, when we found that the only benefit that we

derived from the change of position was increased expense, without any countervailing advantage. The situation turned out not to be eligible; and it is remarkable that the Photographic Exhibition held in these rooms was the only one at which Her Gracious Majesty did not attend with H.R.H. the Prince Consort.

I have to announce that the expenditure of the society has not exceeded its income, and in these days of increased expenditure I think that is, to say the least of it, very gratifying.

I am sorry that I cannot report any large increase of members: we certainly have had no decrease.* I think that precisely the same number have quitted us as those who have joined us; perhaps we have one or two more members now than we had in the beginning of the year.

In speaking of the losses the society has sustained, I have occasion to mention that we have lost the presence and encouragement of Lord Londesborough, who devoted a very large portion of his income liberally to the support of art and science in various directions, and who was a warm friend of the Photographic Society; and I regret to say, also, that we have lost the elder Mr. Ross, whose firm is so well known to every gentleman connected with this society by their remarkable production of lenses for all purposes, either astronomical, photographic, or microscopical.

There was a disagreeable circumstance — I believe the proper mode of speaking of it would be to term it a sort of sore place — which arose out of the supposed occupation of the title of the Society's Journal by another publication devoted to photography. We instituted proceedings in chancery, and all those who know anything about law, and particularly that branch of the law which is called chancery, know that it is better not to go into it, and if you are in, the best thing to do is to get out of it. I do not speak of these matters disparagingly. I assure you that it would be more gratifying to me if I could speak of the law as a study of the greatest delight, and the practice of it as the greatest comfort, and I believe it is so, in fact, to those who occupy a certain position; but when one becomes either as a president of a photographic society or in any other capacity a litigant party, one takes a different view of the subject: it is seen in what is called *another light;* and I am sorry to say we incurred some expenses, and derived very little profit. We must console ourselves, I suppose, by the application of the observations of Dean Swift, with respect to the mistakes that tailors made who measured people by mathematical instruments instead of by the common measure of tape, and so on — everybody was satisfied when he found that his neighbours were in the same position as himself. We have a large number of our neighbours, in common with ourselves, who bore expense and disappointment, and it is very gratifying to find that at length this matter has received what is called an amicable termination.

There was a matter which I mentioned a year or two ago to the society — I mean the discoveries of a foreigner, of the name of Nièpce, who succeeded apparently in bottling light. It was a subject which, in the first instance, promised to be of the most interesting kind; and I own, when first it was announced, it appeared to me to be a step towards very brilliant discoveries with reference to the action of light, and to an investigation of what is the true nature of that medium — if it be a medium — or if we are to go back (and I believe it is going back) to the theory of projection of light, — of what is the course of the rays. One of our most distinguished members is very doubtful of the fact announced in this communication, and I am much in the habit of giving large credence to the opinions of that gentleman in matters of philosophy, and in his own sphere — I mean Mr. Hardwich; but, undoubtedly, there are some in the society, and I believe there are more out of it, who think that the experiments have been so far repeated that they may be considered as successful. It appears to me that it is very desirable that we should ascertain, as far as we can in our own private laboratories (if I may so say), what is the real fact, whether these curious experiments, which really amount to the bottling up of light (for that is what it comes to), are trustworthy. I do not know anything that originally promised to elucidate the theory of vision more than these experiments of M. Nièpce. I repeat that I have the highest respect for the very distinguished member of our society alluded to; but I cannot help wishing, with all my heart, that he may in this instance turn out to be wrong, for I am really very impatient that the Photographic Society should do something more than merely contribute to art, and that from day to day it should more and more astonish the world by its discoveries in science.

Gentlemen, I am very happy to say that I believe the society is safely progressing from year to year: its communications are received, I believe, by the scientific and practical world with greater confidence than ever. We are apparently flourishing. We are contributing, in an eminent degree, to the records of those matters which are of a fleeting character, and which, if they are not recorded by photographers, would perish altogether.

I think I ought to mention that this year we returned to our old room in Pall Mall, and that the photographic exhibition there has been quite successful. H.R.H. the Prince Consort visited it, and expressed himself highly gratified. We seem to be steadily progressing, and I have no doubt that, with your united efforts to do whatever can be done in this direction, prosperity will attend us, and the photographic art will become that which it ought to be—one of the signal blessings to mankind of the present day.

* The Secretary in an audible whisper informed the Chairman that forty new members had joined the society during the past year, and that its present number of members was greater than before.

At the conclusion of the President's address, F. Scrivener, Esq., Warren De la Rue, Esq., Edward Van Notter Pole, Esq., Messrs. Heath, Ruland, Bennett, Claudet, and Telfer, were duly elected members of the society.

The Secretary then read the report, which was duly received; but, as it contained no matter of interest beyond that previously given by the President, we do not think it necessary to give an abstract of it.

Mr. Kilburn was afraid he was not in order, but as his lordship had mentioned the exhibition, he was anxious to ask a question which had resulted from the present exhibition. There were three pictures exhibited under the name of ——* and purporting to be the productions of that gentleman, which were coloured by Mr. Kilburn's own artists, whom he engaged by the year at salaries varying from seven to ten guineas per week. As he apprehended that all pictures at the exhibition were to show the proficiency of the exhibitors, he could not conceive that pictures which were taken at the exhibitors' establishment and coloured by the artists of another establishment could represent that — the fact, unfortunately, was too prevalent. With some of the low members of the art it was the practice to exhibit works at their doors imported from France, but certainly not their own productions. He hoped the committee would withdraw the pictures, inasmuch as supposing the public should patronise the establishment of the exhibitor, he could give no guarantee of excellence, since the artists who painted the pictures were under permanent engagements to him (Mr. Kilburn). Perhaps giving publicity to the trick would meet the exigencies of the case.

The Chairman did not think the meeting could do more than receive a notice of motion.

Mr. Crace stated that the society made it a condition that all coloured photographs should be accompanied with a pure untouched specimen, which was the real standard of excellence — all artistic skill brought to bear upon it afterwards was extraneous; and he thought that this was purely a question beween the two exhibitors and not a fit matter to absorb the time of the society's meeting.

The Chairman asked whether any gentleman would propose scrutineers; if not, he himself would recommend Messrs. Shadbolt and Kilburn.

Mr. Shadbolt suggested a vote of thanks to Mr. Rosling, the late treasurer, which was duly moved, put, and carried.

The Chairman stated that the Collodion Committee had made a report which was upon the table. [See page 48.] If it was the wish of the meeting that it should be read, the Secretary would have great pleasure in reading it.

Mr. Heath: My lord, I may venture to make a remark upon that report. I cannot help thinking that as this evening is devoted to the annual business of the society, it would be a pity, at so late an hour, to enter upon the discussion of one of the most important papers that ever came before the society. Now, whether I shall have the good fortune to carry the meeting with me or not, I do not know, but it appears to me that a paper of that consequence and importance ought to have an evening to itself. I do not speak of the matter in any hostile spirit, but considering the importance of collodion itself, I think that any paper that comes before this meeting as a report of a committee upon that substance, should receive more attention than it can at this meeting. I will go further, and say, that we shall be most jealously and most carefully watched by all societies and photographers throughout England, and all Europe, and before we put our seal, either of approval or not, upon that report, we ought to have plenty of time for consideration and discussion, and I therefore would, with the consent of the meeting, move that this report shall not be read to-night, or published in the Journal, but shall stand over for discussion and consideration at the next meeting of the society. If any gentleman will favour me by seconding that motion I shall be glad.

The Chairman: Will you allow me to suggest that if it be the object to discuss the report at some future meeting, it will be desirable either that it should be placed in the hands of every member separately, or that it should appear in the Journal of the society as quickly as possible.

Mr. Heath: My objection would be, that if that report were published in the Journal of the society, it enters at once upon the transactions of the society, and takes its place just as much as if it had been received and passed as the act of the society.

Mr. Crace stated that it would be the act of the gentlemen whose names were appended to it, and of them only.

Mr. Kilburn moved, as an amendment, that the report be published in the society's Journal, as this course would be more likely to originate discussion.

Mr. Crace: I second that amendment, because I think it the simplest way, and a saving of expense.

Mr. Heath: The Journal goes into the hands of gentlemen who are interested in photography, and who are not members of the society, whereas it would be perfectly simple, if it were intended to raise discussion upon the matter, to supply every member of the society with a copy of the report before the next meeting.

Mr. Shadbolt: I think perhaps Mr. Heath is under a misapprehension

* We refrain from mentioning the name, as their owner was not present, and we do no want to be plunged into an action for libel, which may not have an amicable termination

as to the report. At the last meeting it was announced that the report would be issued, and consequently it will be somewhat stultifying the society if it be not issued. Moreover, there has always been standing in the pages of the society's Journal a notice to the effect that the society could not bind itself to the opinions either of the contributors or even of the editors, consequently there cannot be any mistake as to the report put forward by gentlemen whose names are appended to it.

The CHAIRMAN: Perhaps it would save any further discussion if the motion were carried unanimously, thus:—that the report should be published in the Journal of the society merely as a report, with an intimation that it would be taken into consideration at the following meeting; and, as remarked by a member, such a course will be more consistent with economy, inasmuch as circulating it separately is not without some expense.

The motion, as suggested by the Chairman, was carried unanimously.

The annual ballotting of officers having taken place—

The CHAIRMAN: The scrutineers report that the five members of the present Council recommended to retire are the Rev. J. Barlow, F.R.S., P. W. Fry, Esq., J. D. Harding, Esq., M. J. Rippingham, Esq., and Alfred Rosling, Esq.; and that the members recommended to be elected into their place are Professor Delamotte, J. Durham, Esq., F.S.A., Dr. Arthur Farre, F.R.S., J. D. Llewellyn, Esq., F.R.S., and Professor Wheatstone, F.R.S. The scrutineers also report that the President for the present year is he who has now the honour of addressing you and thanking you for his election. The Vice President is C. B. Vignoles, Esq., F.R.S.; and the Treasurer is A. R. Hamilton, Esq.

The thanks of the meeting were awarded to the Chairman.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

THE ordinary monthly meeting of the Association was held at Myddleton Hall on Wednesday, the 25th ultimo; T. A. BARBER, Esq., in the chair.

After the confirmation of the minutes of the previous meeting, the Rev. James Galloway Cowan was duly elected a member of the Association.

The CHAIRMAN then called upon Mr. Hughes to read his paper.

Mr. HUGHES, after a few preliminary remarks—in which he stated that although he had nothing new to communicate, he had invariably found that those friends who had tried the process he was about to describe met with difficulties and disappointments to which he was a stranger—said that it was with the hope of removing these troubles he was induced to pen the following paper,—*On Toning with Alkaline Chloride of Gold.* [We are compelled to postpone Mr. Hughes's paper till our next number.]

At the conclusion of the paper, a vote of thanks was given to Mr. Hughes, and a discussion ensued.

Mr. D. W. HILL did not find any advantage ensue from warming the gold bath: the strength he used was one grain of chloride of gold to six ounces of water.

Mr. HUGHES replied that with a solution of that strength warming was unnecessary, but if he used one grain of gold to twenty or more ounces of water it would be advantageous; and it was better to use a dilute solution where many prints were to be toned, as they could be all immersed at once, and by constantly removing the bottom one to the top they could be carefully watched, and when sufficiently toned placed in a dish of water at hand. One grain of gold he found by experience would thus tone 500 square inches; and with regard to the depth of tone produced by such a weak solution, he would call attention to a very large portrait on the table, with a broad margin of between two and three inches, which was of as deep a purple-black as could be produced by any process.

The CHAIRMAN hoped that as Mr. Hardwich was present he would favour the meeting with his opinion on the process under discussion.

Mr. HARDWICH said he had looked in on his way home, and had no idea of taking part in the proceedings; nor was he aware that a paper on the subject of toning was to be read. First, with regard to photographic paper, he thought the size used was of as much consequence as the albumen, in the production of colour, and that it would be a great boon to photographers if the subject of sizing were more thoroughly investigated, so as to render them independent of the foreign market. This had been done to some extent, and samples had been sent to him (Mr. Hardwich), but the processes employed had not been divulged. He found that it was possible, with some paper, to use a much weaker sensitising bath than Mr. Hughes recommended—a forty-grain solution being sufficiently strong: it was true he floated the paper for six or seven minutes, until the nitrate of silver could be tasted at the back.

To remove the colour from the sensitising bath he greatly preferred kaolin: he had used salt, but it weakened the solution, and was not so efficacious. The most important subject, after all, was the toning bath. It had been said that the auro-chloride of sodium was all that was actually necessary. This might be the case, and yet, nevertheless, a little alkaline carbonate in excess might modify the colour; such, at all events, was the opinion of Mr. Waterhouse, who first described the process. Citric acid was not an essential ingredient; but he found that by using a citrate he produced a more decidedly purple tint, and it enabled him also to keep the print longer in the bath without its becoming slaty. He believed, however, that much depended on the paper, and he would not be understood to speak positively: it was not a matter of chemistry, but rather of shades of colour, about which no two people would precisely agree. Some succeed more to their fancy with carbonate of soda,—others with phosphate of soda.

Mr. Hughes did not state how long he used the hypo-bath. He (Mr. Hardwich) found that by adding a little alkali he could use it for a length of time. There certainly was a slight trace of sulphuration, as in the sel d'or process, but not enough to affect the permanency of the print. He had used but one bath through the summer; nevertheless it was still in a safe condition, for an ordinary untoned picture immersed in it for half-an-hour remained nearly red. He did not know that he had any thing further to say, unless to express his regret that many persons still continued to use the old process of toning in hypo and gold. An idea just crossed his mind, that if all who wrote on photographic subjects would agree not to publish anything more about the old process it would die out by degrees.

The CHAIRMAN asked if a picture were taken on albumen alone—that is to say, albumen on porcelain or glass—would that picture be red?

Mr. HARDWICH thought it would. There was much in the chemistry of albumen yet to be discovered.

Mr. HUGHES, in reply to the Chairman and other gentlemen, said one would suppose the picture to be in the albumen; but that could not be entirely the case, because the colour of the picture was greatly influenced by the nature of the size of the paper. He had a paper by him which would produce a red tone only, and this was albumenised by himself at the same time with other papers of different makes, and with all the rest he could obtain a deep black violet, violet-brown, or any other tone he wished. With regard to the auro-chloride of sodium, a friend purchased some at one of the best London houses, and he declared he could get no trace of gold on his prints after an immersion of half-an-hour in the bath. He always recommended the use of chloride of gold diluted to a known strength with distilled water. Then, as to the hypo-bath, it was undergoing continual change, much to the consternation of his assistant, who declared that, all through the hot weather, when the contents of other dishes decreased in bulk that in the fixing dish kept on increasing. The fact was, he made no allowance for the water taken up with each batch from the washing dish, when they were immersed in the hypo, and which amounted to a considerable quantity when some hundred were passed into it; his practice was to pour off some of the bath each morning and add crystals of hypo, so that, although he might say he always used the same bath, it was continually undergoing a replenishing; but for the public he thought it best to recommend a fresh bath each time, and of the strength named in his paper.

The CHAIRMAN asked if any member had tried the bi-borate of soda?

Mr. HANNAFORD had tried it, and also the carbonate and phosphate of soda, with all of which the result was the same. The acetate produced a beautiful purple-maroon, precisely similar to that obtained by the use of citrate of soda, suggested by Mr. Hardwich. The acetate has an advantage over the citrate, inasmuch as it can be obtained ready prepared.

A vote of thanks was unanimously accorded to Mr. Hardwich for the part he had taken in the discussion.

Mr. HARE exhibited a swing-back camera of novel construction, also a binocular stereoscopic camera with velvet body, double dark slides, and moveable front; but owing to the lateness of the hour there was no discussion on their merits.

The CHAIRMAN reminded the members that the nomination of officers for the ensuing year would take place at their next meeting, and he hoped there would be a large attendance on that evening.

The meeting was then adjourned to the 29th instant.

N.B.—Those members who have not yet received their Presentation Photograph can obtain it on application to the Secretary.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

A MEETING of the members of this society was held at the Odd Fellows' Hall, Birmingham, on Tuesday evening, the 31st ult., Mr. HAINES, one of the Vice-Presidents, occupying the chair.

The paper for the evening, entitled *Hints Connected with the Dry Processes*, had been contributed by GEORGE SHADBOLT, Esq., of London, Editor of THE BRITISH JOURNAL OF PHOTOGRAPHY, and was read by Mr. BROWN, the Honorary Treasurer. [See page 47.]

In the discussion which followed the reading of the paper, Mr. W. B. OSBORN said that probably few of the members present had had more experience in dry collodion than himself, and more especially with regard to Dr. Norris's process. Mr. Shadbolt's remarks as to the nonsensitive patches caused by white paper on the edges of the plates were quite correct, as these had been noticed by almost every worker with dry collodion plates. The fact was a curious one, and very difficult to be accounted for. If they took one of Dr. Norris's plates, poured upon it a little distilled water, and allowed the water to remain for about one second before pouring it off, they would find that that part of the plate would present on development a perfectly insensitive patch, no matter whether the water was poured on before or after exposure. Then, again, if they carried the plates in a wooden box, or in a box of cardboard, or any other substance which would harbour moisture, the same drawing away of the sensitive portion of the plate was the result. Last summer he (Mr. Osborn) took some dry plates into Wales, and carried them in portable

pasteboard slides; and whether it was that the slides were damp, or from his being near the seaside, he could not positively say, but he found on proceeding to develop the pictures that they had a great quantity of insensitive patches, more especially towards the edges, and also in those parts where they touched the paper slide. This was the more remarkable, because the trial plates which had not been in the slides were quite perfect.

Mr. Norris said he could corroborate the statement of Mr. Osborn. It frequently happened that if they exposed a plate and carried it some distance in a slide, the picture vanished entirely. Of two pictures taken at the same time, one, when developed on the spot and immersed in water, might turn out well, whilst the other carried twenty miles and developed next day, might be a failure.

Mr. Ball: It does not follow as a rule.

Mr. Norris: Unless the slides are varnished or polished, you find great difficulty in developing a picture after long keeping. I think the only safe way of carrying them is in metal slides, which I used fifteen years' ago with the Daguerreotype process.

Mr. Ball: Last summer I took a couple of dozen pictures at Kenilworth, and though none of them were touched for three months, the whole developed well.

Mr. Hart suggested whether, as there was more or less moisture in the atmosphere at all times, the plate might not be robbed of the iodide of silver by the conducting substance.

Mr. Osborn: No, I do not think so; because if you take a dry collodion plate which you have reason to suppose has been over-exposed, you may, by submitting it to the vapour of acetic acid, restore it to a fit state for a second exposure; if the iodide of silver were withdrawn from it you would no longer have any sensitiveness whatever. If you were to take a plate and expose it to full daylight for a second or two, so that it might blacken all over in development, yet by placing it over a vessel containing a little acetic acid, you would destroy all the previous impression, and then you might take a picture.

Mr. Turner: Can you throw any light upon the film rising in blisters? In the albumen dry process I should imagine it is through the collodion being too old.

Mr. Osborn: I think the reason is due to the different contractile power of the two bodies employed, and to the want of sufficient adhesion between the collodion and the glass. If your glass is not absolutely clean you will certainly get blisters in any process; but I believe that in the present case the reason is that the albumen contracts more rapidly than the collodion, and therefore takes up the collodion with it in the form of a blister. The greatest difficulty in working Norris's process is in the washing off of the film altogether, when probably the picture is nearly developed; this is generally due to using an improper collodion.

Mr. Turner said he believed the use of one ounce of a year-old collodion to three ounces of new collodion, would prevent all washing off, and would give a richness of detail which new collodion, say three months' old, would not produce.

The remark of Mr. Brown, that he wished Dr. Hill Norris had been present, led to a suggestion that the discussion should be adjourned, in order to give that gentleman an opportunity of coming amongst them on a future occasion. It was resolved that this should be done, and the meeting on the last Tuesday in March was fixed for the reopening of the discussion. The occasion will be an interesting one, as the merits of wet collodion *versus* dry will be exemplified by the best pictures produced by each process in the neighbourhood of Birmingham. Mr. Breese, a distinguished local amateur, who was present at the meeting, happened to mention that he had never seen a really good picture produced by the dry process—he meant a picture which had atmosphere in it, or any of the higher qualities which the wet process was capable of producing; whereupon Mr. Osborn and others challenged him to produce some of his "wet" pictures, and promised to bring the best "dry" ones they could procure. Mr. Breese accepted the challenge, and as he is probably one of the most successful photographers in England (as the series which, at her Majesty's request, he sent to the Queen last summer proved), the result of this friendly tournament is looked to with much interest.

A hearty vote of thanks to Mr. Shadbolt brought the proceedings to a close.

[This Journal having now become the sole representative of the Birmingham Photographic Society, the reports of that body will, in future, appear *in extenso* in our columns; and, from the arrangements which have been made by the Council to secure papers of great interest, we think the society in a very fair way to achieve success.]

MANCHESTER PHOTOGRAPHIC SOCIETY.

A Meeting of this society was held on the 1st instant, at the rooms of the Literary and Philosophical Society, 36, George Street; Mr. Parry in the Chair.

Mr. Mabley explained that he had not been able to prepare his paper *On the Paper-Printing Process* as he had intended, but would have it ready for the next meeting.

The Hon. Secretary read a letter from Mr. Davies, of Warrington, presenting six photographs for the Society's portfolio; also suggesting that the Manchester Photographic Society might form a Photographic Exchange Club, on a similar plan to the London one, and that he (Mr. Davies) would willingly join such a club.

The plan of the London Club was stated to be something like the following:—A club is formed of a certain number of members, say fifty, each member contributes as many copies of his own negative as there are members, and receives in exchange a copy of each member's contribution, including one of his own, bound up in the form of a book.

The subject was generally discussed and approved of by the members, and it was suggested that those who were willing to join should send in their names to the honorary secretary, and that the subject should be brought before the next meeting for further consideration.

Mr. Cottam contributed a copy of the landscape photograph taken by the panoramic lens.

A very animated and interesting discussion took place on various subjects by those present; and after a vote of thanks to Mr. Parry, for his services in the chair, the proceedings closed at about nine o'clock.

Exhibition.

EXHIBITION OF THE PHOTOGRAPHIC SOCIETY OF SCOTLAND.

Since I last communicated with you I find that your journals and two others reached the address I gave you, to await me in Edinburgh. Circumstances prevented my writing in time for your last publication, as I purposed doing. Since then I have been enabled to pay the Society's rooms several more visits; and I now find that Mr. Brady's (New York) picture, No. 269, is labelled "*touched picture*," perhaps in consequence of the remonstrance in your Journal. An addition has also been made in the interim of a portrait of John Brown, the noted Harper's Ferry martyr. He is a tall, brave, noble-looking fellow, with independence stamped by nature on his manly brow; as physically strong in limb as inflexible in purpose, and worthy the respect of every conscientious man and philanthropist.

I shall begin my remarks with Mr. H. P. Robinson's (Leamington) compositions. They have, no doubt, cost much trouble and great care, yet they are not effective or pleasing to the eye. There is a vacuity and emptiness, both of subject and detail, in nearly all of them, and often an incongruity in their several parts. It requires a peculiarly constituted mind to grasp and delineate, in an imposing manner, ideal pictures assimilated to nature, so that the several parts shall be proportionate in degree, and in keeping with the subject designed to be illustrated. I am, notwithstanding, happy to observe that the Society has awarded its first medal to Mr. Robinson's picture (No. 470), *Here they come!* in consideration of his untiring perseverance in this branch of the art, there being no other competitor in the field for pictures of this class.

Mr. Mudd, of Manchester, takes the other medal for his picture (No. 627), *Waterfall near Coniston*. This is a remarkably fine picture, and pleasing in every respect. It is an excellent composition—grey, time-worn rocks, over which a small cascade of water is falling in the immediate foreground, with glorious far-reaching undulating mountains in the distance, melting into the sky, conveying sublime emotions to the mind of the vast and glorious works of the great Architect of nature. Mr. Mudd contributes various other excellent pieces—such as No. 521, *Dunham Park, Cheshire,*—a study embracing lofty trees, with a winding avenue amongst the stems, bordered on each side by the green shaven sward, cooling to the feet and refreshing to the eye.

There are several excellent picked copies of Fenton's works, not sent by himself, but introduced by one of the dealers here. They are fine, rich landscapes—woodland and river—on the Hodder. They are clean, well-defined prints, fully equal to anything I have seen from his hand of late.

Messrs. J. Dixon Piper, Henry White, and Maxwell Lyte, all send good pictures. No. 529, Mr. Piper's *Gainsborough Lane, near Ipswich*, is a beautiful specimen, and perhaps the choicest of his contributions in landscape. But he excels also in architectural subjects. Nos. 265, *Abbey Gate*, and 292, *Norman Tower, Bury St. Edmund's*, are without exception the finest specimens of architecture on the walls. There is scarcely any observable aberration proceeding from the curves of the lens; the lines are nearly perpendicular, all in good focus, and the proofs altogether are very choice and effective.—Mr. Lyte's pictures are mostly mountain scenery in France. They want breadth and atmosphere; they are by the metagelatine process, and greatly inferior to Mr. Mudd's.—Henry White remains steadfastly attached to his Scotch firs and corn-fields. I should like to see the result of his trying an ash, or silver birch, "The Lady of the Woods," with its quivering leaves. I

have seen an ash and willow tree here, though not in the Exhibition, most perfect in the foliage, and the leaves beautifully distinct.

Mr. Morgan, of Bristol, sends some artistic specimens, the composition good, with fine aërial effect; but I think they are scarcely up to the mark of those exhibited by him last year. No. 674 is excellent, and has in it the elements of a rich landscape: a light, lofty Roman arch, overhung with ivy, the water in little streamlets gurgling through amongst large rounded stones, with high, rising, naked, barren rocky cliffs in the distance. Several other by this artist are very successful studies.

There are very few albumen proofs. The most choice specimen is by Mr. M'Pherson of Rome — subject, *The Forum, Rome,* well known among the dealers.

Maull and Polyblank, as usual, send a large quota of heads, two being office-bearers in the Scotch Society: — Sir David Brewster, the President; and William Walker, Esq., a Member of the Council. Sir David Brewster's portrait wants life and animation: it is more like the portrait of a statue than of an active, intelligent mind. Some are better, but all are indebted to the brush.

There is a curious selection of Indian subjects by Mr. Williamson, principally rows of figures in the same plane, entirely void of atmosphere and distance — such as *Indian Chiefs;* a *Hindoo on his way to be executed;* a *Mahomedan Priest; Religious Devotees;* a *Hedge School,* &c. They are curious for loungers to look at, but scarcely serve any other purpose.

The President of the United States—an enlarged portrait by Brady — is on the same screen, and in another frame a considerable number of his senators, combining every variety of countenance. But the gems are two heliographic pictures by Charles Negre, exhibited by the Manager of the Kensington Museum. They are large plates, representing the gorgeously elaborate architecture of the mediæval age. The proofs are taken from steel or copper, which is shown by the indentation on the paper. If these are really untouched specimens, and can be produced by the ordinary methods of steel and copper-plate printing, they indicate a very rapid progress.

The Messrs. Hay, as I mentioned before, send a large number of portraits, several of which are very creditable productions, but are inferior to those by Rodger.

Messrs. Brady (New York), Messrs. Cramb Brothers (Glasgow), and Mr. Ramage (Edinburgh), all try their hands at enlarging from smaller pictures. I would advise any one having a respect for his natural countenance to forbid this experiment.

Messrs. Kirk, Zeigler, and Walker all exhibit some pretty landscapes. The former sends the scene of one of the poet's choicest melodies—

"Sweet fa's the eve on Craigie burn."

This is a beautiful specimen of foliage in a deep dell, taken during a profound calm, nature being in perfect repose. It is the only paper proof exhibited by Mr. Kirk by the wet collodion process. — The other two gentlemen named above both exhibit views on the Esk, by the waxed-paper process. In this locality there appear to be some lovely spots well adapted for the panoramic lens.

Mr. McCraw seems to be devoting his energies to stereotyping public bodies and corporations, such as the Town Council and St. John's Kirk Session.

There is an other advantage to be gained by Mr. McCraw's taking the matter in hand: he can print by the everlasting positive ink process without silver — as witness No. 130, *The Scott Monument,* and a very excellent proof it is.

There are many more pictures deserving to be prominently noticed, especially those of Mr. Rodger, of St. Andrew's, whose portraits of Master and Miss Gordon (No. 87) have been awarded the ten pounds Maconochie Welwood prize. All his pictures are of the very highest class — "*peers in their own right.*" In pose, drapery, light and shade, detail, atmosphere, ease, and gracefulness, they are all that can be desired. Mr. Rodger is the veritable prince of photographers of all that exhibit in Scotland. Mr. McLeay paints well; but Rodger's works are more artistic and beautiful, without and entirely independent of the brush.

Mr. Moffats keeps his ground, and furnishes portraits of several well-known citizens, in chaste and pleasing attitudes.

Mr. Tunny is set down by the *Edinburgh Scotsman,* in a piece of sly sarcasm, as the "FATHER OF PHOTOGRAPHY;" I presume because a claim was put in for him as the discoverer of collodion in some of the Photographic Journals, better than a year since. Be this as it may, he exhibits a frame principally containing groups, packed with heads like herrings, making one rub his eyes as if he had been reading a double column of small print, for several hours by gas light. The *Grange School* must contain somewhere about a hundred faces, nearly all having *very small eyes:* they are by the wet collodion process.

Mr. Horatio Ross has had assigned to him the office I expected would have devolved upon the secretary — that of awarding the medals.

I believe a new society is greatly needed in Scotland, both for the purpose of encouraging the beautiful and fascinating art of photography, and for making suitable arrangements for properly exhibiting the productions of professional men (many of whose works are banished from the *line* to the lobby), since with the exception of *three or four,* they have all left the society, notwithstanding the secretary's disclaimer in a late number of a contemporary. SEL D'OR.

[We have received letters of complaint from Mr. Valentine, of Dundee, relative to the hanging of his pictures in the exhibition above noticed, which he asserts are, with one single exception, hung so high as to be almost invisible — the excepted one being the worst of the series. He also states that he received an uncourteous reply to his remonstrance.

None but those who have tried it know what an invidious task it is to arrange the works in any exhibition; but when space is limited the difficulty is enormously increased; — the pictures you want to be together wont fit, and those you desire to separate will; besides many other perplexities.

We trust that Mr. Valentine has been the victim of circumstances, rather than, as he supposes, intentionally slighted.—ED.]

Practical Instructions on Coloring Photographs.

By ALFRED H. WALL.

CHAPTER VI. *(Continued.)*

HATCHING.

This is a process of working with oblique lines, forming lozenge-like apertures, and indicating by their degree of curve and regularity the form and character of the surface represented. The lines should taper to a point at either end, as they then blend better into an uniform mass. In line engravings and chalk drawings, hatching exhibits great power of expression, every line representing the alternations of the surface and being capable of describing its texture; but in flesh these lines by being repeatedly crossed in different directions assume all the appearance of a stipple, and thus serve to express the smoothness as well as the transparency of flesh.* Carefully avoid crossing the lines at right angles, as you would then obtain the effect of net-work, and do not make them long. Commence with short, broad, tender touches, placed at regular intervals and in a nearly horizontal position, beginning with a rather firm pressure and finishing with a lighter one; with the same touch cross these lines horizontally and repeat the process at slightly varying angles until the requisite depth is secured. Avoid leaving little blotches of colour at the ends of the lines, and do not cross one set of lines with others until the first are dry. The part where the lines intersect will of course be darkest, but should not be strikingly so. Hatching is a far more artistic mode of working than "stippling," but the latter is frequently blended with the former to increase the "smoothness," or what is vulgarly and erroneously called "finish." Stippling is, to my thinking, only legitimate when it is used to even up any small space which has been left too light in the process of hatching.

STIPPLING.

What some folk would do without stippling I dont know, for like charity it "covereth a multitude of sins" — sins against common sense — and every quality of truth. It is painful to the real artist to hear the high praises constantly lavished upon productions breaking every rule of art, and displaying no better quality than that evinced by patiently and laboriously dotting over with a pin-point pencil a certain small space of paper. I'm sure I ought not to denounce it, for when I first began to experimentalise upon the public, that same mechanical stipple did me a world of good service; and there are many very worthy fellows, profoundly ignorant of painting, who support themselves most comfortably and with an immense amount of self satisfaction upon their stock of patience, dealt out in the shape of stipple to an admiring public at the rate of so many guineas per square inch.

Stippling, then, is simply the covering of a surface with a vast number of minute touches or dots.

It is of course much easier than hatching, and *perhaps* by its adoption you may obtain smoothness and softness—qualities which

* Hatching enables you as it were to look below the surface, or in other words gives that depth which could never be obtained by repeated washes.

I have no fault to find with if they do not blind the student to those of a much higher order, are in their proper place, and do not originate that thoughtless laudation which is so seriously dangerous to real progress. Most of the worst-drawn pictures I ever saw were stippled highest, and there is nothing in the use of this stipple which may not be won by the veriest "aprentice han," if its owner will not grow weary of the interminable and monotonous dot, dot, dot, dot, dot, of the process. Hatching educates the hand and eye, and implies a knowledge of form and texture. Stippling educates neither, and implies a knowledge of —— what? For rudimental study at least, therefore, pray adopt the method of hatching.

The author of the preceding paper has, in order, to render his communications of greater practical value, kindly undertaken to criticise the work of, and give advice to, students in colouring, through the medium of these pages, for which purpose specimens may be sent, with a stamped and directed envelope *for their return, to* A. H. Wall, Esq., 11, The Terrace, Walworth.

Despairingly (Margate).—After inspecting your coloured print, and reading your sensible and pleasing letter, I consider you, on the contrary, a very promising pupil. I like to hear of difficulties recognised and courage sometimes daunted: it shows the courage to be real and the power great. Now for the advice:—In the first place, your eagerness to make good progress defeats its purpose; to be "*sure*" you must be "*slow.*" This I glean from the touches being much too hard and dark (which, had they been made by continual repetitions, would not have been the case), and by the lines being hard and cutting, which, had they been commenced faintly and strengthened gradually, would also not have been the case. Take a dose of patience, and begin again: you must walk before you run.

E. G. *or* E. J.—The latter portion of the above reply will answer this correspondent and "A Poor Gentleman," to which I must add, for the benefit of the last-named, that photographic colouring *is* remunerative, if it be well done. I know an artist, colouring for a first-class London establishment, who receives fifteen hundred a year; and I have heard of even higher salaries being paid. About three hundred a year I should say.

A Mechanic.—Why not? If you have the taste and ability you need nothing but industry, patience, and perseverance. I am glad to have been of such good service to your friend the photographer.

Miss D—— (Kingsland).—Read the reply to "Despairingly." Paper positives are not managed so easily as glass. The print is a very good one for the purpose. Your glass positive displays great improvement. The writer you speak of being evidently well acquainted with his subject, will doubtless be of use to you; and, whatever he may say of the "absorbent" colours, he will not exceed what Mr. Newman deserves, in praising the powder colours sold at that gentleman's establishment. For my own part, nowever glad I might be to tender my tribute of praise, I should (upon the score of good taste) certainly hesitate to denounce, in such terms, the productions of any special manufacturer. When I used dry colours I prepared most of them for myself, but have lately purchased them.

Robert Davis.—I intend to re-publish these instructions in a separate form, but not exactly in the way suggested. The hint is, however, worth consideration, and I may act upon it. If so, I shall be happy to forward any number of copies—"the more the merrier." Send it when finished: I can then judge better.

Dodsworth.—A failure. Re-read the instructions with more care and attention, and begin again. I am glad you appreciated the paper in question. I know the gentleman well, and respect him much: please to remind him of my whereabouts.

Ann Page.—The pictures have not yet reached me.

G. R.—If you forward me a specimen I shall be enabled to judge.

Foreign Correspondence.

Paris, February 10, 1860.

Mr. Omegauck, of Antwerp, states, as a fact of his experience, that a clean plate of copper, such as is used by engravers, heated to 250 to 300° Fahrenheit, and placed in the camera during the exposure of a collodioned plate, will diminish the time of exposure two-thirds, and will be found very useful in cold weather. I give you this as I received it: not having tried it I cannot say in how far it is correct.

A new *Photometer* has just been introduced to public notice; it is the invention of Signor Givi, Professor of Physics at the Technological Institute of Florence. He calls it the *Photomètre analyseur.* I will give you a brief description of it. The idea of this photometer was suggested by the difficulty we encounter whenever we wish to compare together two differently coloured lights. In this instrument the comparison is made only between rays of equal refrangibility. The principle upon which this photometer is constructed is easily understood. It must be premised that the lights to be compared are not simple. If such present themselves for examination, the judgment of several persons must be brought to bear upon them, and the mean of the opinions of all must be taken, for every eye does not see different colours alike.

The photometer consists mainly of a prismatic box, elongated horizontally, and having two openings in each of its vertical (and smaller) sides. In these openings two tubes are adjusted, each having a slit at its extremity; and in the middle of the box, exactly in the direction of the two slits (which are vertical), are fixed two rectangular icoseles prisms of pure glass, placed so that their hypothenuse sides are opposite each other, while two sides being vertical, the other meets by the acute dihedral angle, and form a horizontal plane. Above these prisms is an achromatic lens, large enough to admit the entire beam of light which, coming from the two slits, is refracted through the prisms. The rays which have passed through the lens are received upon a large equilateral prism of flint glass, which is brought by a gentle movement to a position which gives the minimum of deviation to the mean rays of the spectrum. Leaving the prism, the dispersed rays fall upon a plate of ground-glass, placed perpendicularly to the mean rays of the spectrum. By this disposition, two spectra of equal length are obtained, and touch each other by the borders. When it occurs that the two slits receive rays of equal intensity, then two spectra appear as one; but when one source of light is more powerful than the other, with which it is compared, it must be removed to a certain distance, until the required effect is obtained.

I have lately seen some portraits taken by a Voigtlander lens of five inches aperture. They are truly splendid, in size, vigour, sharpness, and brilliancy: the whites are pure, and the darks are remarkable for the delicate gradations of colour they show. I consider nothing finer, or even so fine as these, has ever been exhibited. The artist is Colonel Komaroff. J. P.

Correspondence.

THE REPORT OF THE COLLODION COMMITTEE.

To the Editor.

Sir,—The business of the annual meeting of the Photographic Society having occupied so much time and attention last evening, I conceived that it would be desirable, looking at the importance of the subject, to adjourn both the reception and the consideration of the Report of the Collodion Committee, and I moved this adjournment accordingly.

Perhaps you will now allow me to explain, for the information of those who were not present, that in adopting the arrangement that was come to, by which the Report is to be published in the Journal of the 15th inst., and the discussion upon it adjourned to the March ordinary meeting, it was thoroughly understood that this publication is made in strict accordance with the following rule of the society, viz.—"That in printing papers presented at the ordinary meetings, the Council does not thereby adopt the views or opinions of the authors."—I am, yours, &c.

43, *Piccadilly, February* 8, 1860. VERNON HEATH.

HOW TO ECONOMISE OLD TONING BATHS.

To the Editor.

Sir,—I was lately requested to examine a product obtained from alkaline chloride of gold toning baths, and as the result of the analysis may be useful to some of your readers, I have much pleasure in placing it at your disposal. My friend had been advised to collect his waste solutions, and to throw down the gold from them by sulphate of iron. He did so, and obtained a bulky deposit, which was washed and dried in the usual way. Before sending it to the refiner he enclosed two drachms of the dry powder in a letter to me, asking my opinion of its value. I send you by this post a brilliant little button of pure gold extracted from the powder, which you will find, on dropping it into the scales, to weigh nearly ten grains and three quarters.

In addition to the gold a small quantity of chloride of silver was present, but the great mass of the powder consisted of carbonate and peroxide of iron. The analysis was rendered more troublesome by this large excess of iron, and it at once occurred to me that my friend must have had a very bulky precipitate to deal with in the first instance, and that I might save him some trouble by giving a few directions. It is the carbonate of soda contained in the toning bath which throws down so large a quantity of the iron salt, and this may be entirely prevented by converting the carbonate into chloride of sodium by the addition of hydrochloric acid. Every drachm of the dry sesqui-carbonate of soda will require about a fluid drachm and a-half of the commercial hydrochloric acid, after which the re-action to test paper will be decidedly acid, and sulphate of iron added in excess will precipitate nothing excepting pure gold.

The above method, in which the carbonate of soda is neutralised, although correct in theory, is not to be recommended to the amateur photographer, inasmuch as the deposit of gold is apt to adhere to the sides of the bottle; and not only so, but it appears so small in quantity that an inexperienced person might easily be led to throw it down the sink as worthless.

By making the proper calculation you find that chloride of gold requires nearly six times its weight of sulphate of iron for its reduction, supposing no alkali to be present; but if this quantity be added to the alkaline toning bath, the deposit is so abundant that it seems at first to fill the whole of the bottle. I have, therefore, made a series of experiments to determine the smallest possible quantity of sulphate which may be used.

If to a solution of one grain of chloride of gold, with thirty grains of carbonate of soda, in six ounces of water, there be added a single grain of sulphate of iron dissolved in a drachm of water, the supernatant liquid will be found after vigorous stirring to contain gold still unreduced. A second drachm of the sulphate of iron solution leaves only a trace of gold, scarcely weighable, whilst a third drachm (making three grains of sulphate of iron in all) completes the reduction.

The precipitate as thus obtained is small in quantity, and subsides without any difficulty: after settling down for twelve hours it occupies not more than one-twentieth part of the total bulk of the liquid, and when dried weighs about two grains.

I am, yours, &c., F. HARDWICH.

SPOTS IN NEGATIVES, &c.

To the Editor.

Sir,—Last summer, when practising the wet collodion process for negatives (being quite a novice in the art), I began by giving too long an exposure, but the plate had just the appearance of being *under* exposed, with numerous opaque spots all over it, so I went on adding to the time till I counted forty, and the longer I exposed the more the appearance of *under* exposure increased, merely the highest lights showing, the shadows black without any detail. At last a friend set me right by telling me to count three, which I did, and although that was rather too long, I got a passable picture the first time, with every detail perfect. I still find a difficulty in getting a portrait without those small opaque spots.

If, sir, you can inform me of the cause of the above, or whether in certain states of the bath, collodion, or developer, such appearances are usual, I shall esteem it a great favour.—I am, yours, &c.

Salisbury, January 30, 1860. AN AMATEUR.

P.S.—Seeing some time back, in the pages of a contemporary, an ingenious but complicated contrivance for storing prepared plates or negatives in the plate box without scratching the film, the idea occurred to me, that if the grooves, instead of being made square, were bevelled, it would answer every purpose and be quite as easily constructed as the old plan.

[We cannot explain the first portion of your letter, and have never found over exposure to produce clean shadows without any detail, but rather the contrary.

The plan for grooves which you suggest has been long in use.

As for the spots, we advise you to clean out your slide very carefully, and see that the French polish does not scrape when the door is raised.—Ed.]

PREPARATION OF OXIDE OF SILVER.

To the Editor.

Sir,—Will you oblige me by stating in your next number of The British Journal of Photography how to prepare oxide of silver for the purpose of correcting an acid negative of silver bath? I find it very good for that purpose, and as it is better freshly made, I should like to make it myself.

I thank you for former favours, and am, yours, &c.

J. G. S.

[Dissolve a drachm of nitrate of silver in four ounces of distilled water, and drop into it a solution of caustic potash, made by dissolving any quantity of that substance in eight times its weight of water, more or less. Continue the addition of the potash, with continual stirring, until an olive brown substance settles down, and the milky liquid above gives no further deposit on the addition of more potash. Then fill the vessel up with water, and when the powder has subsided pour the liquid off and fill up again. Do this three times, when the oxide will be sufficiently pure for your purpose.—Ed.]

"P. L."—INDEX.

To the Editor.

Sir,—In your number for November 15th, 1859, on page 282, is Mr. Heywood's paper on "Toning Positive Prints." In the formula No. 2, he says "chloride of sodium (P. L. strength):" will you be so kind as to say what "P. L." means?

While I have pen in hand I take the liberty of suggesting that your "Contents" would be much more useful if they gave the *principal subjects* discussed at the various meetings, as well as the page on which they are reported—especially when any formulæ are given, or *practical experience;* as, for instance, in January 1st number, page 13, is given the method of "transferring to leather." This increased usefulness would be even more apparent in looking over back numbers or volumes.

I am, yours, &c., F. B.

January 27, 1860.

["P. L." means the London Pharmacopæia. The material indicated is, however, not chloride of sodium, but chloride of soda, a preparation analogous to that of chloride of lime.

We fear that to give such an index as you propose would be impossible, and it would certainly be very bulky.—Ed.]

BAUMÉ'S SCALE.

To the Editor.

Sir,—You would much oblige by enlightening me, in your next issue of The British Journal of Photography, upon the following points:—What is meant by rectified ether 62°, rectified alcohol 40°, and "azotic cotton?"—I am, yours, &c. R. PEERS.

[Azotic cotton is nothing more or less than pyroxyline—*id est,* cotton with a portion of "azote" or nitrogen in its composition.

As regards the strength of the spirits, we rather think that the degrees refer to Baumé's scale. If so, the ether would be of specific gravity ·734 and the alcohol of ·830.—Ed.]

A QUIET QUIZ.

To the Editor.

Sir,—I have been somewhat puzzled by a paper on a new dry process, which appears in the last number of your usually very correct Journal. It seems to have been read at the last meeting of the Photographic Society in "Auld Reekie," and, if you report it correctly—as no doubt you do, after what you had to say on this subject very recently—I can fancy the amount of useful information those members present at the meeting must have carried away with them, after giving their attention to so very concise a paper. Dr. Paterson, of Leith, who claims the honour of introducing this valuable new dry process, goes on to say, that "it is his distinct conviction that no collodion film will give anything but uncertain results without some preservative solution;" but I have sought in vain for a hint of the valuable decoction which the Doctor finds so satisfactory and uniformly successful. He lays much stress on a certain kind and thickness of collodion, and we are told that this collodion consists of sulphuric ether and alcohol, with a mixture of the iodides of cadmium and potassium, and bromide of cadmium—nothing more. Pyroxyline has nothing whatever to do with it. The plate must remain a certain time in a bath of certain strength—*to wit:* Silver 40 grains, *acetic acid* 20 *grains, water* 1 *ounce*—truly this will be sour enough to "*mak' the dogs yowle;*" and the given quantity of water with which the plates are to be washed is left ungiven; so that one does not much wonder at the Doctor being named as one of the Society's committee who are to examine and report on this and other dry processes, giving the preference, of course, to the *Doctor's own.*—I am yours, &c.

Edinburgh, Jan. 26, 1860. *VERY DRY.*

[See our reporter's correction in the present number.—Ed.]

ANSWERS TO CORRESPONDENTS.

T. D. B.—Chloride of ammonium.

Park Lane.—Take No 3 on your list.

France.—We must decline to accede to your request.

J. H.—The same developing solution will do.

W. R.—We cannot advise. You must judge for yourself.

Fairfax, Jun.—See our last number of the past year.

O. O.—Your process is not at all new.

R. S. T.—Consult Hardwich's Photographic Chemistry.

J Morris.—A bellows camera is the most convenient.

XX—Refer to the Index of last year's volume.

Argus.—Your suggestion shall be attended to in our next.

Nemo.—Your inquiry is answered in No. 110.

C. B.—*Nil desperandum.* Try again: you have been too hasty.

Exton R.—A metal camera would doubtless meet your requirements.

James Curland.—Your negative has not been sufficiently developed.

C. J.—Harvey's portfolio is just the thing for you. (See our advertising columns.)

George.—The alcohol causes the developing solution to flow freely over the plate.

Quidnunc.—At the Exhibition of the Photographic Society of Scotland, now open.

Operator.—Received too late for insertion in this number, but shall appear in our next.

Otto.—It was a typographical error, but so palpable that we did not deem it worth correcting.

A Perplexed One.—You had better make a new bath, or add half new to half of the old.

Alex.—Read the articles on Fixing Positives, by Messrs. Davanne and Girard in current numbers of this Journal.

Samson.—Your proceedings come under Lord Campbell's Act against obscene publications. You had better retire from that business.

Chas. Cave.—We never made any such assertion, for we never heard before of the maker you name. It is a pure fabrication.

Evening.—Develop with iron solution, and strengthen (subsequent to fixing) with pyrogallic and citric acids.

Cadmium.—We prefer iodide of this base for collodion for amateurs as a rule, though it certainly causes it to be a little more gelatinous than with an alkaline iodide.

Φωτο.—1, We think that you might obtain the material you require by applying to any of the operative chemists who advertise in this Journal. 2. Nitrate of silver is extremely soluble in water: sulphate of silver and acetate of silver both sparingly so. Lactate of silver and fluoride of silver are also soluble.

J L. F.—1. We do not know anything of the maker you name, but the cameras you inquire about are made by Ottewill & Co.—we need scarcely add, well made. 2. Much depends upon the lens employed; if thoroughly adapted for the purpose, there is no doubt that you may do what you inquire about. That which will do well for portraits will do better for your purpose.

F. Watts.—We not only *think* it possible for a Photographic Society where the subscriptions are small to afford to each member a good photograph annually, but *know* that it can be done—*e.g.*: the North London Photographic Association has accomplished this every year during its existence. (See report in our present number.)

C. A. G.—1. It must depend partly upon your object. If for landscapes only, we should employ the collodio-albumen process; but if figures are desired, we fear this would not be satisfactory. Smartt's tent, to be had of Murray and Heath; Burfield and Rouch's tent or box; Shepherd's tent and camera, are all good. Apply to each for an illustrated description, and choose which you find best suited to your requirements. 2. We believe not, especially if Taupenot's process be adopted. 3. Melhuish's metal one.

Simple Simon.—1. See reply to "C. A. G." 2. The fixing of the plates may be deferred until you return home, if you take the precaution of dipping a brush in some quickly drying varnish, and running it round the edges, before wetting the film a second time with water. This will prevent the collodion from splitting or curling off. 3. Perhaps you could not do better than commence your practice with the Fothergill dry process, on plates of the stereoscopic size. 4. We advise you to make the camera slide of well-dried mahogany; but the body of the instrument may be of deal, if you study economy. 5 Hardwich's "Photographic Chemistry," 5th edition. John Churchill, New Burlington Street.

*** We regret to be obliged to postpone till our next number the Second Notice of Mr. Frith's splendid work, "Egypt and Palestine;" also Mr. Hughes's paper *On Toning with Alkaline Chloride of Gold*, and the conclusion of the article *On Fixing Positive Proofs.* By MM. Davanne and Girard.

☞ *All* Editorial *Communications*, Books for Review, *&c., should be forwarded to the Editor*, GEORGE SHADBOLT, 2, *Upper Hornsey Rise, London, N.*

All Advertisements *and* Letters *on the* Business *of this* Journal *should be addressed to the* Publisher, 32, *Castle Street, Liverpool.*

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 113, Vol. VII.—MARCH 1, 1860.

In another column we publish a letter from an "Overworked Operator," appealing to those who have the power, urging them to grant the boon of a weekly half-holiday to the unfortunates who are compelled to spend the bulk of their time in a dark room, inhaling the deleterious fumes there so abundant, but from whom, nevertheless, artistic skill is required.

In a precarious climate like our own it may seem no small thing to ask of a professional photographer that he should give up say one-twelfth of his possible stock of sunshine; but is this so? In the first place, we very much doubt whether there is not, as a rule, one day in the week when sitters are not numerous in the afternoon; but even if we err in this opinion, it would not take long to make the public aware that portraits are not to be had on some particular day. The employer will naturally ask, what he would gain by the concession sought? We think he would gain extra diligence from those he employs during the rest of the week, and in addition superior excellence in their productions. We do not consume the whole produce of our harvest as food: we lay by a portion for seed, wherewith to sow in hopes of a next year's crop. Now this weekly half-holiday, if granted to the operator, will, we consider, be like the corn laid aside for seed, wherewith a rich harvest of artistic skill may be reaped in the following week. Surely some amongst our professional brethren will try the plan for a week or two as an experiment. If it succeed, why of course they will continue the practice; if it fail, they will not have lost much at any rate. But lose they will not. We feel assured that they will at least receive a *quid pro quo*.

It has been suggested to us that very much labour would be saved to energetic workers in the various branches of photography if we were more frequently made acquainted with photographic failures, and that our advance would be thereby rendered both more rapid and more certain. That this would really be the case we cannot doubt, for, by adopting the exhaustive method in any inquiry, we could not fail of success, provided that success were possible. Next to being acquainted with the right road, it is of advantage to know the wrong one, in order that we may avoid it. We know that many, if not most photographers, do not care about recording their failures, but they need not do this by name; and if once convinced of the utility of the practice, we have considerable hopes of its more general adoption. We are very often applied to for advice how to get out of certain photographic difficulties, but it rarely happens that the cases are stated in such a way as to make them available for general instruction. With very little trouble, however, to our correspondents, they might frequently be of great assistance to those younger brethren of the art who are always on the look-out for an available hint. We are informed very constantly that our "Correspondence" is read with the greatest interest, not only by novices, but by "masters in our art." Even they sometimes pick up a hint; but, apart from that, there is the pleasure of "fighting their battles o'er again." We are convinced that our "Correspondence" may be made still more useful than it is even now if our readers will only bear in mind that "one good turn deserves another." In the last number of the *Journal of the Photographic Society* is an excellent article on Actinometry, by Mr. Barnard S. Proctor, yet that article is composed principally of a record of unsuccessful experiments. Truly one man's failure is sometimes better than another's success.

We have noticed upon two or three occasions, some little time back, a circumstance which demonstrates no little want of morality in the perpetrator, and which has excited the attention and animadversion of a transatlantic contemporary. We allude to the appropriation of articles culled from certain photographic journals by an individual, and republished by him as original, and with his name attached to them, in a certain American photographic periodical. But this is not even the whole of the offence, for though complete sentences and even paragraphs are copied *verbatim et literatim*, certain alterations are made which not only frequently destroy the sense altogether, but often, nay, generally, upset the grammatical construction of the remainder, and indicate that the perpetrator of the outrage is as little blessed with education as he is with honesty.

A straw thrown up will indicate the quarter whence the wind blows, and a few chips will mark the course of the current: so matters apparently of little moment are sometimes highly significant. The time was when the accomplished editor of the *Athenæum* occasionally gave insertion to a piece of photographic intelligence, provided it contained something very new, in a patronising way, but quite pooh-poohed the possibility of *art* in connexion with it. Now and then, too, when a photographic exhibition was opened, as a sort of encouragement some notice was taken of it in a "stenographic" kind of manner; but recently we have been not a little gratified at finding that photographers have been favoured with a regular critique or two, much in the same style as is adopted with exhibitions of paintings. We have noticed also that the writer of the said critiques understands more of photography than of yore, though even now he sometimes confuses over-exposure with under-exposure, and evidently is not quite clear which is which. The conclusion that we draw is, that photography is certainly a progressive art.

In a paper recently read before the Photographic Society of Scotland, by Dr. Paterson, he said:—"From a careful microscopic inspection of plates prepared with these two processes, I am satisfied that we shall never get good results, after a short space of time has elapsed, without having a preservative solution to the collodion."

This is an expression of opinion, not a statement of a fact, and therefore open to question—not that we are about to question it, but we cannot help regretting that the Doctor omitted to state

why he came to this conclusion, and what were the appearances which he noticed that led to this conclusion; because, had he so done, others could have argued upon the point, and either confirmed or controverted the opinion as the case may be. We have on many occasions submitted collodion films to microscopical examination, but have been quite unable to detect any appearances sufficiently different between "preserved" and "unpreserved" films that would, in our judgment, lead to such a conclusion.

We are happy to find that our Liverpool friends are about to be regaled with a Photographic Exhibition, in April next, under the auspices of the Liverpool Society of Fine Arts, in connexion with a general Ancient and Modern Art Exhibition. The photographic section of the Historic Society of Lancashire and Cheshire has promised its aid in furthering this object, and our energetic friend, Mr. J. A. Forrest, is taking an active part in the matter. We trust that many of our noted exhibitors, professional and amateur, will aid in making the collection such an one as will fairly represent the present advanced state of the art.

In our last we noticed the omission of the editor's name from the title-page of a contemporary photographic periodical; since then, some of the particulars which led to this proceeding have become public property, having appeared in the law reports of the *Times* and other newspapers. We believe, therefore, that we are not guilty of any impropriety in now stating that the publication to which we made allusion is the *Photographic News*, and the name of the editor Mr. William Crookes, which name has been suppressed. It appears from the "report" mentioned, that a misunderstanding having arisen between the editor and proprietors of the periodical named, in consequence of the alleged unauthorised alteration by the latter of some articles written by the former, the editor "moved for an injunction" before the Master of the Rolls, to restrain the proprietors from making and publishing alterations in his articles, and also from removing his name from the title-page.

It is well known that Mr. Crookes has recently undertaken the editorship of the *Chemical News*, a proceeding which appears to have given offence to the proprietors of its photographic namesake,—and the whole matter was further complicated by an agreement existing between the respective parties concerned extending over a considerable space of time. The judgment of the Court was against granting the injunction prayed for, the *alterations* complained of being similar in character to others permitted on previous occasions, and, in the opinion of the judge, *improvements;* the editor's name was not regarded as a portion of the title as contended; and an action at law was directed to be tried unless the dispute should be settled out of court—the costs to be "costs in the cause." The name of Mr. Crookes has not been replaced; and we have but little doubt, judging from a perusal of the recent numbers, that he has ceased to perform the editorial functions.

PHOTOGRAPHIC CONTRIBUTIONS TO KNOWLEDGE.

"EGYPT AND PALESTINE:"

By Francis Frith—*Illustrated with Photographs.*

[Second Notice.]

Many of the illustrations in this valuable collection we have already noticed in our columns when criticising the contents of the various photographic exhibitions held during the last two years in the metropolis, and where all are so admirable it is a somewhat embarassing task to make a judicious selection for special comment. We do not, however, think we should be doing justice to the excellence of this important publication were we to omit altogether such a proceeding. We shall therefore select for the purpose the following:—

Temple of Koum Ombo, Upper Egypt.—This is one of those gigantic ruins that call forth in the spectator as much astonishment at the magnitude of the structure as admiration at the beauty of design and picturesqueness of effect. The figures of two Nile boatmen leaning against one of the enormous stones which formerly constituted a portion of the freize, indicate the immensity of the proportions of the edifice, which in its turn dwarfs the figures to the aspect of Liliputians. The massive pillars are buried in the shifting sand of the desert almost up to the sculptured capitals, which support an entablature with devices of two winged globes, emblematic of the omnipresence of the deity, and which are plainly visible. Beautiful, majestic, magnificent even in its degradation—what must it not have been in its glory!

Pharaoh's Bed, in the Island of Philœ.—Mr. Frith says: "The Island of Philœ is the most beautiful thing in Egypt, and the temple absurdly called Pharaoh's Bed is the most beautiful thing upon the island." From the very exquisite photograph with which he has enriched this collection we are by no means disposed to question the correctness of this statement. The singular structure of the temple, built without any roof (none being needed in this splendid climate), forms the apex of the composition. Clumps of the date palm trees, with their naked stems and feathery tops, harmonise with the pillars and their leaf-like capitals. At the foot of the mound on which the building is erected, the waters of the Nile appear, with one of the native vessels, called a "dahibieh," moored in a sheltered nook; the whole composing into a most effective picture, albeit one of a very uncommon character. The execution of this specimen is little, if anything, short of perfection.

Sculptured Gateway, Karnac.—This Pylon, as it is termed, consists of a species of triumphal arch—but that no *arch* exists, the opening being rectangular, and the whole structure tapering upwards. Over the gateway is the winged world, before mentioned, while every part of the exterior surface of the building is covered with hieroglyphics.

The Great Column and Smaller Temple, Baalbec.—We instantly recognise these columns as the model or type to which a host of imaginary picturesque ruins owe their existence. That they *are* beautiful, very beautiful, few will be disposed to deny; but *why* they are so it is not so easy to point out. The proportions of the columns and their relative distance apart, perfect as these are at once *felt* to be, are not enough to explain the charm that undoubtedly exists, for this is materially heightened by the terribly dilapidated state of the crumbling stone. Perhaps it may be in some measure owing to the beautiful chequering of light and shade, similar to that we observe in a grove of trees. We are not at all learned in architectural mysteries, but the capitals of the pillars appear to us to be of the kind which we have been taught to call "Corinthian."

We perceive that Mr. Frith indulges in a little *piquante* pleasantry on the subject of architectural nomenclature.

Nazareth from the North-west.—This is an illustration in which everybody is sure to be interested, and is perhaps the most effective of all the distant views. The locality in which Our Saviour spent the greater part of his life on earth is situated in a kind of fertile valley or basin, at a high level amongst a series of rounded undulating hills. Though a little deficient in vigour, this is an extremely pleasing photograph. The immediate foreground is occupied by a hedge of "opuntia," or "prickly pear," a member of the cactus tribe, beyond which Nazareth, with all the peculiarities of an Eastern city, is displayed to view, whilst the background is composed of the wooded slopes of the distant hills, which assume a more and more rugged aspect as the eye ranges over the higher levels; and across the summits of those hills, forming the natural basin on which the city is built, a dim outline of still more distant ridges is perceptible.

The Largest of the Cedars — Mount Lebanon. —Apart from the interest attaching to this subject in an historical point of view, it is one which is valuable as an illustration — not only for botanical puposes, but also to the artist — of the habit and aspect, as well as of the habitat of these celebrated timber trees. The proof before us is beautifully executed, and the composition pleasing and artistic.

The Temple of Wady Kardassy, Nubia, is truly, as Mr. Frith terms it, "a bonnie little ruin." It seems to have been constructed on purpose to form the centre of a picture, as it does in the one before us most completely. Located on the river's bank, with the calm waters of the stream reflecting the wooded slopes of some low hills on the opposite bank, it conveys a perfect sentiment of repose, no doubt partly owing to the deep but transparent shadows caused by the flood of light from an unclouded sun. This is a picture that will please all tastes, possessing as it does a charm apart from association.

The Circular Temple, Baalbec, is an architectural gem; and, what is more, it is disposed in a picturesque setting, situated in a pleasant locality. With reference to a "delicious stream," along the bed of which he rode knee deep in approaching this temple, the artist quotes the following lines :—

"So bright the pebbles on its shore,
That not a maid may thither stray,
But counts her stringed necklace o'er,
And thinks the pearls have slipped away."

Assouan — a town on the banks of the Nile, situated in the most romantic spot of the Nile Valley, in the immediate vicinity of the first cataract and the islands of Elephantine and Philœ — is no less interesting as a landscape. The town is, as it were, imbedded in a luxuriant grove of date palms, and is backed by a low range of distant hills, while the windings of the river form a graceful foreground, prettily broken up by a number of passenger and merchant vessels moored alongside the beach, which is strewn with such merchandise as ivory, bags of gum, and other similar produce, whilst a crowd of natives occupy a point of land near some of the vessels. It is altogether a very pleasing composition.

With so many attractive illustrations, it is difficult to know where to stop; but as we have already extended this notice far beyond our usual limits, with one more we shall conclude it.

The Doum Palm and Ruined Mosque, Philœ, is equally worthy of commendation with the last-named, as a picture; though the subject is perhaps as markedly in contrast with it as it is well possible to be. It is a ruined mosque on the steep side of a rugged, picturesque rock, with the palm tree in the foreground, the fruit of which tree, we are informed, constitutes the nut employed for making small articles of turnery ware, and known as vegetable ivory. We cannot resist the following quotation from the letterpress annexed to this specimen :—

"It may interest my brethren of the Black Art (as my mother calls it when she overhauls my shirts as they come from the wash) to know something about my apparatus and *modus operandi*. Know then, that, for the purpose of making large pictures (20 inches by 16), I had constructed in London a wicker-work carriage on wheels, which was in fact both camera and developing-room, and occasionally *sleeping-room;* so that the doctor whom I heard at the Photographic Society a year or two ago ridiculing the rage for large pictures, and proposing as the *ultima thule* of extravagance which his playful fancy could suggest 'that men should have their cameras upon wheels, and large enough to sleep in' (a remark which raised a hearty laugh through the room), committed an error common with wits — his remark was much less facetious and imaginative than he supposed.

"This carriage of mine, then, being entirely overspread with a loose cover of white sailcloth to protect it from the sun, was a most conspicuous and mysterious-looking vehicle, and excited amongst the Egyptian populace a vast amount of ingenious speculation as to its uses. The idea, however, which seemed the most reasonable, and therefore obtained the most credit, was, that therein, with right laudable and jealous care, I transported from place to place my — harem! It was full of moon-faced beauties, my wives all! — and great was the respect and consideration which this view of the case procured for me!"

We have already mentioned the handsome manner in which this work is "got up." The printing, both typographic and photographic, is of the highest order. As regards the former, it is of a most readable size, clear, and not too crowded, and the initial letter of each page is elaborately ornamental; respecting the latter we can truly affirm that it is about as near to perfection as possible. The whole of the proofs have been executed in the establishment of Messrs. Frith and Hayward, under their personal superintendence, and we have reason to know that there is every probability — not to say almost certainty — of the *permanence* of these photographic treasures,—the system pursued in their production embracing all the most approved manipulations, and the colouring matter of the pictures consisting of gold.

Messrs. Frith and Hayward have recently removed their extensive printing establishment to Reigate, where they have erected every appliance for the production, on a large scale, of first-class photographic proofs, for the illustration of this and other important publications, as well as for general photographic printing. We are of course not at liberty to mention the extent of their resources for the production of a large number of copies in a given time; but we may state that it is astounding, and goes further to convince us of the stability of photography as "an institution" than the concurrence even of many other favourable indications.

We cannot conclude without expressing a hearty wish for the commercial success of this publication, of which we have been endeavouring to convey to our readers some adequate idea.

Those who feel inclined to inspect the views can at present do so at Messrs. Leggatt, Hayward, and Leggatt's, in Cornhill, London, where the whole series, mounted and framed, is on view.

REMARKS ON PHOTOGRAPHIC PRINTING AND THE ALKALINE GOLD TONING PROCESS.

By Mr. Hughes.

[Read at the North London Photographic Association, January 25th, 1860.]

It is certainly unnecessary, in introducing the subject of photographic printing, to occupy any time in showing its importance. The more diffused our art becomes, and the more extended and varied in its applications, the greater the necessity that its productions should be as perfect and as permanent as possible. Thanks to the many photographic chemists who have devoted their attention to this subject, foremost among whom is Mr. Hardwich, the theory of photographic printing has made rapid advances; but I am inclined to think that photographers generally have not attached sufficient importance to these investigations, and that, especially in everyday practice, they have not profited to the full extent by the knowledge thus placed before them. Far be it from me to say that any method has yet been given out by which prints may be guaranteed to be permanent; yet many processes have been largely practised, and are not even now abandoned, which in their very nature are calculated to yield only temporary and fading ones. The object of the present paper is to call attention to the different methods of toning and fixing, to advocate strongly what the writer believes to be a superior method of printing, and to show that there is no difficulty in reducing this method to practice; likewise to bear the testimony of nearly two years' experience that it is suitable for all the wants of the practical photographer.

It is but a few years since that a wail of despair arose, when most of the brilliantly toned prints of that time were found to be fast fading. An appeal for help to stop this plague was made to the chemists, who were asked to explain this fading, and to show how to avoid it. Help soon came, and it was proved that the fading was caused by the sulphur compounds generated by the use of old acid hypo in the toning and so-called fixing baths. The cause once known, many plans were suggested to remedy the evil, and from that time the prints improved. But the question now arises: Have we sufficiently profited by our past experience? Do we, in our daily practice, take advantage of all the knowledge that has been placed within our reach? Though every intelligent photographer affects the greatest horror of toning by sulphuration, and few will be found to advocate the old method of forming a toning bath by adding blackened chloride of silver and free acid to hypo and gold, yet in what respect does the common practice differ from

this, when commercial chloride of gold (always containing free acid) is added to hypo, and the prints taken direct from the pressure frame and immersed therein? Nitrate of silver added to hyposulphite of soda invariably produces decomposition, liberates sulphurous acid, precipitates sulphur, and produces all the conditions necessary for sulphuretting action. Let not the photographer then hide the fact from his mind, that by immersing his unwashed prints in the solution of hypo and gold he is producing, whether he intend it or not, a toning bath by sulphuration. Whether nitrate of silver be added to the bath concealed among the pores of the paper, or visibly in the form of crystals, the result must be the same.

But here allow me to hold an imaginary conversation with a photographic friend, who interrupts me by saying—"Yes! but when I put my unwashed prints into my toning bath I get good colours." "Admitted," I reply; "but mainly, if not entirely, due to sulphur." "But," says he, "I added gold to my bath, one grain to the ounce." "Exactly; and this by its acidity assists in producing the sulphuration." "But," exclaims my friend, "what am I to do then—wash my prints first?" "Yes." "But in such a case they tone so slowly—how is that?" "Because you are trying to tone by the action of gold alone and without sulphuration." "Why cannot I succeed? Everybody talks about toning by gold." "Because you have hypo present, which retards the action of the gold; moreover, you are mixing up two distinctly different processes—toning and fixing." "How should I do then?" "*Use the gold without the hypo for the toning, and the hypo without the gold for the fixing;* in short, don't mix up two processes which are by their nature dissimilar." "Tell me how you would proceed." "Listen;" and here my paper properly begins, but from the above you may infer that I am no advocate of the gold and hypo toning. I consider it to be theoretically imperfect and practically delusive; while I esteem the other, or alkaline gold toning process, as theoretically correct, and as practically the nearest approach to a perfect printing process. My assistants and I have practised it nearly two years upon all varieties of prints, large landscapes, small stereoscopics, portraits large and small, on the most highly albumenised and on plain paper. I find it capable of giving all desirable varieties of tone—warm chestnut brown, purple brown, or purple black.

In many of my friends' hands it produces equally good results. Moreover, I have found it so easy, certain, and regular, that had I not heard of others experiencing difficulties in working it, I should scarcely have felt warranted in introducing it to you. I am, however, so impressed with its superiority, and so anxious that it should be generally practised, that I crave your indulgence if I appear unnecessarily minute in the particulars. The choice of the paper is important—more so in this than in the usual printing process. It is only necessary, however, to have a clean, well albumenised paper, with a fine hard face, that will retain the albumen on the surface rather than in the pores. A paper that presents a dull woolly look will seldom give anything but a flat, dead picture. The paper itself, apart from the albumen, in this as well as in other printing processes, undoubtedly modifies the tone and general aspect of the finished picture. Saxe and Rive papers have given me the most brilliant pictures: of the two I prefer the former, since it is the most free from metal spots, and being rather larger, cuts up more advantageously. The amount of glaze on the surface may be varied with the taste of the operator, but the finest prints are certainly to be obtained on the highest albumenised paper; in fact, there is no process so well adapted to give rich tones on the very highest glazed paper as the one now described, since the extra amount of albumen, though offering no obstacle to the toning, materially assists in giving a fine rich colour. To those who albumenise their own papers I may mention, in passing, that the more concentrated their albumen the smaller the proportion of salt they will need, and where albumen alone is employed, from five to eight grains per ounce of chloride of sodium or ammonium will be enough; but since most persons purchase their paper already prepared they will be spared this consideration.

To sensitise the paper, float it for about four minutes on the silver solution, dry quickly, and use as soon afterwards as convenient. I attach great importance to keeping the silver sensitising bath in good order. I make it about sixty grains to the ounce; I test it, and if it be acid I neutralise by carbonate of soda, and add one drop of glacial acetic acid per ounce. This keeps the whites of the print clear, and prevents the solution acting on the surface of the albumen. If more acid than this be present, or even as much of nitric acid, great difficulty will be experienced in toning. This fact I have established frequently—that a strongly acid silver bath greatly impedes, if it does not entirely prevent, the deposition of the gold in this process. I believe it also to be of the greatest consequence to keep the silver solution up to the required strength, for if the solution be weak the prints will be poor and flat. Few persons are aware, unless they have tried it, how rapidly sheets of paper rob the solution of its silver. To prevent mistakes on this point, I recommend in every printing establishment, and to all amateurs, the use of the silver-bath meter. This little instrument, made on the principle of the hydrometer, has only to be immersed in the sensitising solution, and the number of grains per ounce it contains will show at the line where the surface of the fluid touches the tube. The merit of this little instrument is its simplicity. Without professing analytical accuracy, or the perfection of more complicated instruments, it is sufficiently correct for all practical purposes, and no knowledge of chemistry is required for its use. It is always ready, needs no calculation, and the dullest boy can employ it. The general plan adopted, of throwing in a few crystals after some sheets have been sensitised, just as the operator may fancy, can lead only to the most irregular practice; for he is at one time working with a needlessly strong solution, and at another getting weak and dim prints, blaming, perhaps, the paper, when the fault lies in the weak solution.

I had a pupil once, who sent to me, from the country, for some albumenised paper. He took a few prints, and all went well. But after a time he wrote to say that the last few sheets of the paper were not so good as the first, and that he wished for some more like the first sheets, assuring me that there was a difference. The same paper was sent again, but the reply came, "very bad indeed—worse than before." As I knew the paper to be first-rate, daily using it, I asked to see the faults; and when the dim, weak, and mottled prints came, I surmised the cause. I sent a bath-metre, and invited my correspondent to try his sensitising solution: he did so, and found that it stood at twenty grains per ounce. He had been using strongly albumenised paper on a solution of twenty grains, allowing it to remain on two or three minutes, and was astonished that he did not get bold and clear pictures. He strengthened his solution to sixty grains per ounce, and then the paper he had condemned was found to be all he desired. Although this is an extreme case, yet many may be daily troubled in a lesser degree from the same cause.

It will not be possible to continue using the silver solution without its turning dark coloured. The remedy is the use of kaolin. If two or three ounces of this substance be shaken up in a bottle with the discoloured solution, and allowed a few hours to settle, it will be found to be its proper colour again. I keep a few ounces of kaolin at the bottom of my stock bottle, and at night the solution that has become discoloured by use during the day is poured back and well shaken up with the kaolin, and in the morning I find it decolorised, settled, and ready for use again. It is then tried by the silver metre, and fresh crystals of nitrate of silver are added in the proportion required to bring the solution to the standard of sixty. Thus the solution is always kept in a uniform condition.

Newly precipitated chloride of silver has a similar property of decolorising the silver bath. A few drops of a solution of clean household salt, therefore, added to the bath, and the curdy precipitate well shaken up, does the same work as the kaolin. I have used both these methods, but prefer the kaolin, as being more economical and effective; still there are circumstances, such as when kaolin cannot be obtained, where chloride of silver will be very useful.

According to the ultimate tone desired, so should the print be exposed. If a warm tone be wanted, some of the shades of purple brown for instance, then the printing must be carried a little deeper than you would like it to remain; but if a rich purple black is required you must print much deeper, and the deepest shadows should be slightly bronzed. Do not examine the prints much in daylight, or the pure high lights will suffer; keep them in the dark or yellow light till you are ready to tone and fix. My practice is to print during the early and middle parts of the day, placing the prints as they come out of the pressure frames in a drawer secluded from the light. In the latter part of the afternoon I collect my prints, and commence by cutting off all the blackened and bronzed margins, preserving the paper, the silver from which, together with filter papers and other scraps, I afterwards recover by burning. Three dishes are then placed beside each other; the prints are one by one immersed in the first till all have been put in, allowing them to remain, say five minutes, and then placing them in the second dish, moving them about, that the water may get well between them, again leaving about five minutes, afterwards removing them into the third dish and allowing them to remain a few minutes longer. The object of these several waters is to wash out all the free nitrate of silver from the paper. The last water should be

only *slightly milky;* if it be more than this the prints must be further washed. These waters are then poured into a large vessel, and some solution of household salt added. The nitrate is thus converted into chloride of silver, which precipitates. This is allowed to remain undisturbed till the morning, when the chloride having settled at the bottom the clear water is poured off from the top, and the vessel is ready to be used again for a similar purpose. The chloride thus daily accumulates until it is in quantity sufficient to be worth sending to the refiners for sale. This in the end will be found cheaper than attempting to reconvert it into nitrate of silver oneself. By this means a very considerable amount of the expense of printing may be avoided. After the prints have been well washed some persons recommend that they be immersed in weak salt and water, others suggest dilute ammonia. I have tried both, and can find no advantage in either, and have therefore abandoned them. The prints are now ready for the toning bath, which is composed as follows:—

Chloride of gold	1 grain.
Carbonate of soda	10 grains.
Good household water	8 ounces.

These, unlike the gold and hypo solution, may be mixed in any order. For convenience I always keep my chloride of gold in a solution of known strength, say the usual fifteen grains in fifteen ounces of water: every ounce of solution then contains one grain of chloride of gold. It is advisable to warm this toning bath, as its action is thereby rendered more rapid, especially in winter time; but it must not be made too hot, or the gold will be precipitated. If the solution be heated so that it is just warm to the fingers it will be sufficient. The prints must be put in individually, and be kept constantly moving about. Those put in first will rapidly tone to a purple tint. It is necessary to watch the prints as they arrive at the proper tone, and then remove them into a dish of clean water. Most persons who begin this process tone their prints too much, so that when they are finished they have a faded, cold, bluish look. If they be not toned enough they will be of a brown hue, the happy medium lying between these two extremes. For beginners in this process, I recommend to put not more than ten prints at a time into the toning bath: let them turn these over and watch them, and take each out, and place it in the dish of clean water, as it arrives at the desired tone. When the whole ten are done, then put in another ten, and so on, since when the operator has had more experience he will be able to manage a larger number at a time in the bath. The toning will take from two to five minutes, according to the depth of colour desired and the number of prints in the toning bath at one time. No more toning solution should be mixed than is necessary to be used at the time, as it will not keep. In order to judge of the quantity of solution that should be mixed, I give, as the result of careful and long continued experiments, taking one variety of picture with another, that one grain of chloride of gold used in this manner will tone five hundred square inches. As a whole plate contains about fifty square inches, one grain will tone ten prints of that size, or twenty-five stereoscopics.

By keeping the chloride of gold in solution, and taking advantage of the above rule, a person may easily calculate how much toning solution he requires.

The prints removed from the toning bath to the dish of clean water, are now placed in the fixing bath, formed of

Hyposulphite of soda	1 ounce.
Water	7 ounces.

Allow them to remain in ten minutes or a quarter of an hour, frequently moving them about. Wash them well in the careful manner that is usually recommended (and most persons have some pet plan of their own); but they should have many changes of water during the first hour, and one at least for every hour afterwards. When the prints are placed in the hypo they usually lose some of the purple hue; but, if they are properly toned, this rich colour will return to them on drying. The above quantity of hypo solution will last for two or three moderate batches of prints, when a new one may be made, or fresh crystals be added to the old one. If this latter plan be adopted—and it is a very general one—a little prepared chalk or carbonate of soda should be added to the fixing solution, so as to keep it faintly alkaline; it thereby loses the sulphuretting action it might probably acquire by continued use. The process I have thus minutely described I strongly recommend to photographers as being the best that exists. My assistants and I have produced some thousands of prints with it. I have a heap of them here, done more than twelve months since, from which you can judge of the varieties of tone. These prints have lain loosely in a drawer; and although the time that has elapsed is nothing in proving their stability, yet it is satisfactory to think that so far there is no indication of change.

Theoretically this process is the most perfect we yet have, and brings this part of our art more within the reach of definite principles; for we have fewer of those mysterious and complicated chemical actions, and each portion of the operation is separate and distinct from the rest. The print is taken from the pressure frame, and, the nitrate of silver it contains having served its purpose, is first washed out. Gold is then deposited on the reduced silver, improving the colour and, judging from reason and analogy, aiding the stability of the print; next, the chloride of silver still remaining in the paper is dissolved out by the hyposulphite of soda; and, finally, with careful and copious washings the hyposulphite is sought to be got rid of. Every stage is clear, simple, and easily understood.

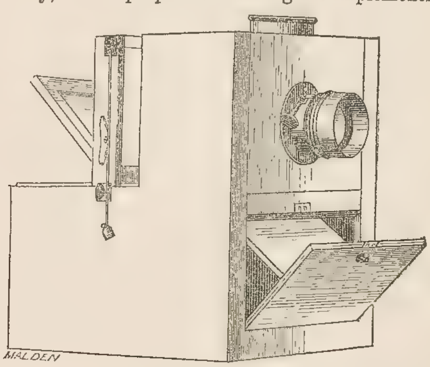
Practically it is the best, because it is more economical in time and money, gives the richest tones, allows considerable variety, and, greatest of all, affords a hope that with ordinary care its results will be as permanent as they are beautiful.

PHOTOGRAPHIC DEVELOPING LABORATORY.

By Titus Albites.

[Communicated to the French Photographic Society.]

The object of this apparatus is to enable unskilled operators to execute the collodion process in the open air, without the aid of tent or dark room, and in a manner so easy as to be almost mechanical. The apparatus consists of a camera [see cut], the lateral sides of which are prolonged so as to form a box of dimensions double those usually given to cameras. The upper half consists of the usual working parts of a camera; the lower portion forms the laboratory. The back portion of the camera, which serves as a frame, contains a fixed gutta percha dish and the nitrate of silver bath, which is concealed in the laboratory. This bath, as may be understood, moves with the frame, and is drawn up with it when slid. A cord, which is seen at the side of the camera, held in position by a counterpoise, sustains, in the middle of the frame, a piece of silver intended subsequently to hold the collodioned plate. In front, beneath the lens, a door opens which admits the hand into the laboratory, for the purpose of working the implements, &c.



To employ this apparatus, proceed in the following manner:—The door beneath the lens being closed, lower the shutter of the frame, and focus upon the ground-glass in the usual manner. Remove the focussing glass, and substitute the collodion plate, which is kept in its place by the piece of silver fixed to the upper part of the frame. By detaching the cord, placed on the outside, which sustains this piece of silver, the glass is allowed to fall by its own weight into the silver bath beneath, as before explained. Raise it, then immerse again and again, until it is completely sensitised. About twenty to twenty-five immersions are necessary and sufficient for this purpose. The plate being now sensitised and restored to its proper position, the cap is removed from the lens, and the necessary exposure given. Then replace the cap on the lens, and cover the plate with an india rubber cloth; detach the silver hook that sustains it, then seizing it by the extremities, incline it, and make it pass into the developing bath placed at a certain inclination within the laboratory. The sides of this bath are formed of yellow glass, and receive the plate in a groove, which prevents it touching the sides. Then open the door beneath the objective, when the screen falls upon the developing bath, which contains the plate, so as to prevent the light injuring it. The bath, which is composed of yellow glass, is then lifted out of the laboratory, and

its arrangement admits of the developing being proceeded with in the open air, the operator watching it through the coloured glass.

Among the principal advantages the inventor claims for his apparatus, M. Albites especially urges that of suppressing the usual slides, and consequently less risk of spots and stains appearing; also that the sensitised plate is acted upon immediately it leaves the silver bath, and consequently diminishes the time of exposure.

ON VARIOUS KINDS OF GLASS, WITH REFERENCE TO THEIR APPLICATION TO PHOTOGRAPHIC PURPOSES.

By J. A. Forrest.

[Read at a meeting of the Liverpool Photographic Club, February 14, 1860.]

The most important use of glass in photography is, undoubtedly, for the sensitive tablet; therefore, to have a clear apprehension of its nature and qualities, it will be necessary for me to describe the process of its manufacture. I will not enter upon its component parts until I treat the subject with reference to its use for photographic roofs. There are only two kinds of manufacture, viz., crown and sheet: both come under the head of blown glass, but the processes are essentially different. In "crown" the glass is wrought into a flat circular table, with a "bull's eye" in the centre; and in "sheet" into a hollow cylinder, which is cut in the direction of its axis, and then unrolled into a flat rectangular "sheet," of uniform thickness. Both kinds of glass are frequently made from the same furnace of "glass;" but as crown glass has been made for a longer period, I will first describe its manufacture, and then proceed to sheet glass.

The first workman is called the "gatherer." It is his duty to take up or "gather," upon the end of an iron blowpipe, sufficient "glass" to form a table of the size and weight required, the average diameter being fifty-two inches, and the weight thirteen or fourteen pounds. The blowpipe is about six feet long, and one-and-a-quarter inch diameter in the body, with half-inch bore from end to end. The mouthpiece is turned of a convenient shape, and a handle is formed adjoining it, by wrapping cord upon the pipe until the diameter is increased to about two inches: it is then covered with a thin layer of cement. The "glass" is "gathered" upon the extremity, "the nose"—the pipe for about four inches being expanded gradually like a cone. The "nose" is heated by an attendant boy, who hands the pipe to the "gatherer;" he walks up to the furnace, and through a hole in the side—the "working hole"—he dips the "nose" of the pipe into the "glass" in the "pot," and by turning the pipe round "gathers" a quantity of "glass" upon it. The weight that can be "gathered" depends greatly upon the state of the "glass" as to fluidity: the stiffer and cooler it is, the greater the quantity that can be taken up at once. At the commencement, when the furnace is very hot, three successive gatherings are generally necessary to obtain enough "glass" for a "table;" but as the furnace soon cools, the majority are "gathered" at twice. Of course, before "gathering" a second time, the "first time" is allowed to stiffen and cool. A great deal of skill is required in the "gatherer" to keep his "gatherings" concentric with the pipe, and of a regular shape, and to gather his second and third times at proper intervals. If the "glass" were, so to speak, lopsided, the air bubble would not pierce it in the centre, and the table of glass would be untrue in shape, or thicker on one side than the other: so also irregularity in the shape of the "gathering" would cause irregularity in the size and thickness of the "table." These faults are avoided by a constant and careful rotation of the pipe upon its axis, the tendency of the semifluid mass to bend downward being continually counteracted by the turning, which obliges it to bend itself straight again, and this motion of the pipe is continued incessantly, in various degrees of speed, from the instant the pipe is dipped into the "glass" until the "table" is delivered complete to the kilnman for annealing. During the "gathering" the pipe has become heated from the "glass;" it is, therefore, cooled by a stream of water, and the workman then proceeds to the gatherer's "marver." This implement was originally called a "marbre" (a flat slab of marble being employed); it now consists of a plate of polished cast iron, elevated about twelve inches from the ground. He rolls the "piece" to and fro on the polished "marver," bringing the front to an obtuse angle; the pipe is then lowered considerably, and the hinder part of the piece is rolled or "marvered" in the same manner as the front. The form thus obtained is one which experience has shown to be the best suited to the acquisition of a circular plate or "table" of as equal thickness as possible. The point ultimately forms the "bull's eye" or "bullion."

The shape being perfected, and the glass of a proper consistence, a boy blows forcibly down the pipe, and the "piece" assumes the shape of a spear head, having a hollow in the centre, and is carried by the boy from the "gatherer" to the "blower." The small air bubble, left for the purpose of keeping open the bore of the pipe, or the contraction of the iron, would so fasten the "glass" in the aperture that no human lungs would have power to force a passage. From very obvious reasons it follows that the larger the opening or bubble containing air, the easier is the blowing, hence the very small bubble for the "marver boy" to commence upon, and the stiffness of the glass renders his blowing the hardest in the whole process, and he is obliged to hold in his cheeks with his hands, or the muscles would become so fatigued he could not blow at all. This post is taken in turn, for short periods. The "piece" having passed into the hands of the "blower," he reheats it through an aperture in a small reverberatory furnace, called the "Patteson hole:" the derivation of this name is unknown to me. As soon as sufficiently heated, the man carries the piece to the "blower's marver," similar in every way to the gatherer's marver, and having hung the "piece" downwards in the passage, it elongates. The point is straightened upon the marver, and then resting the pipe upon the edge of it, the "piece" projecting beyond, he rolls it to and fro, gently and gradually blows down the pipe, and swells the "piece" to the form of a large pear; the point now taking much more the "bullion" shape. It must be borne in mind that the hottest, and, consequently, the softest portions of the "piece" expand most when blown out, and that the thickest portions keep hot the longest, and in reheating the thinnest parts are soonest heated. It can thus be conceived, how by waiting until it is somewhat cooled, or by blowing most at first—how by hanging down and drawing out, or keeping up and running in—and how by clever management of the rotation of the pipe, centrifugal force may or may not be called into play—I say it can be conceived how, by these and similar means, an adroit workman regulates the thickness of various parts of of his "piece."

[We regret being obliged to postpone the remainder of this paper, and accompanying diagrams, till our next Number.]

Meetings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of the above society was held on Friday, the 17th ult., in the Lecture Hall, Walworth; the Rev. F. F. Statham, B.A., F.G.S., President of the Society, in the chair.

The minutes of the last meeting were read and confirmed.

Mr. Wall, Hon. Sec., said he would tender no apology for calling the attention of any members not cognisant of the same, to the fact of Mr. Lake Price being upon the eve of publishing a series of papers upon *Composition and Chiaroscuro in their Application to Photography.* Photographers had yet to learn the real value of their beautiful art, apart from its purely scientific elements; and he hoped the articles in question would do much to elevate and refine photographers, and (through them) photography. While on the subject, he might perhaps be permitted to add a few words upon some articles appearing weekly in one of the journals, under the heading of "Backgrounds: how to paint and arrange them." Certainly nothing could have a greater tendency to lower photography to a "penny plain and twopence coloured" species of art, than these papers—written, beyond doubt, by one who in theatrical parlance is called "the stage property man"—degrading the character of the periodical in which they appear, and offending all readers possessing the smallest quantity of good taste. Having an especial abomination of "white skies," will you also permit me to call attention to a letter in this day's *Photographic Journal* from Mr. Collie, in which he states that he secures natural clouds in his pictures by first developing until the sky is out, then washing, and again re-developing the parts not sufficiently done. To restrict the solution to one particular part seems to require no little skill and care, but it is a hint worth notice.

The discussion upon a paper read at the previous meeting by Mr. Leake, jun., was then resumed. [See page 34.]

Mr. Hannaford asked if the gentlemen who undertook to provide specimens in illustration of their remarks at the last meeting had done so?

The gentlemen in question not having brought such specimens,

Mr. Herve said Mr. Leake's experience tallied so closely with his own, that he should merely refer to the absence of one common cause of failure in that gentleman's list, viz., that arising from immersing the plate too quickly in the bath.

Mr. Hannaford: A question was raised at the last meeting as to whether anything would be gained in the time of exposure if the picture were first brought out by iron, and afterwards intensified by pyrogallic acid. From some experiments he had made, he was inclined to believe that the advantage in this respect was not so great as was generally supposed.

Mr. Hughes, being present, would perhaps favour the meeting with the result of his experience on this subject.

Mr. Hughes regretted his absence at the reading of Mr. Leake's paper, and said, with regard to the question of development with iron and pyrogallic acid, that his own experience was somewhat involved, inasmuch as he was not prepared to say in unqualified terms whether, under all circumstances, much was gained in the time of exposure by the use of the iron developer. Developers varied greatly with the nature of the collodion used. Bromide in the collodion and pyrogallic acid as the developer necessitated a long exposure. Archer's collodion, iodised with four grains of iodide of potassium to the ounce, produced, when newly iodised, equal results with both the iron and pyro. developer; but when it began to lose its sensitiveness, and became, say a deep sherry colour, the iron certainly proved the better developer, giving details in the shadows, when the pyro. failed to render such detail altogether. Take any collodion and bromidise it, and a remarkable change will be produced. The iron will then bring out the picture with excellent half-tone very quickly with a short exposure, which must, however, be materially increased if pyrogallic acid be used as the developer.

Mr. Hannaford, to test this matter, exposed a plate with collodion containing a maximum of bromide, and afterwards developed the two halves of the picture separately, the one half with iron, the other with pyrogallic, and found, by so doing, that while he gained nothing in the details of the shadows by using the iron in preference to pyrogallic, yet it gave a cleaner picture, and brought it out under retarding circumstances of temperature. Mr. Hannaford promised to make a series of experiments in this direction, and bring down the results to the next meeting, as a continuation of the "Photographic Jottings."

Mr. Tear had tried the experiment Mr. Hannaford named, and got excellent detail with the iron, while the pyrogallic gave nothing but a bad positive. It was true that he had not tried them on the same plate, but the exposure had been the same. As he had purchased the collodion (negative) he could not, of course, speak as to its nature.

Mr. Leake thought, with Mr. Hughes, that the time of exposure was determined as much by the nature of the collodion as that of the developer, and spoke of an instance in which he found the ordinary pyrogallic developer acted with greater rapidity than the iron. But for portraiture, at least, he held iron to be far preferable, as giving cleaner, clearer, and more uniform results.

Mr. Howard had found during the late unfavourable season, that it was only by using iron that he could procure a picture at all, and that by its use he could procure one with half the exposure needed for the pyrogallic developer. He used Thomas's collodion. Mr. Leake had referred to the development of dry plates with iron, and he had certainly found it very useful. As an amateur, with but little time for experiments, he should be glad to know of a test for the bath more certain and definite in its results than litmus paper was stated to be in Mr. Leake's useful paper.

Mr. Hannaford thought the test paper sufficiently sensitive for all ordinary purposes, but not, of course, for baths where instantaneous pictures were required, and gave the following plan:—A bath for ordinary work should contain acid in sufficient quantity to render its effect on test paper readily perceived. If, however, it were desired to obtain a bath as nearly neutral as possible, the best way would be that recommended by Mr. Leake; but the plate need not be exposed in the camera, it would be sufficient to stop when the plate no longer threw down a deposit of silver.

Mr. Hughes suggested a slight modification of Mr. Hannaford's plan, and explained that, as there was always more or less tendency to reduction if you sensitise a plate and admit light to any portion of its surface, the effect would be confined to that point, and would prevent the irregular reduction which might tend to mislead as to the state of the bath: a portion of the plate ought, therefore, to be exposed to light.

Mr. Simpson thought Mr. Hughes's suggestions rather tended to get the bath in good working order than to get a neutral bath, which was the real purpose of the discussion. The process just recommended *might* issue in getting a thoroughly acid bath. After all, the question of neutrality or acidity of the nitrate bath was unimportant, compared with the necessity for having it in good working condition.

Mr. Hughes said he was curious to know why Mr. Leake had lost faith in test-paper.

Mr. Leake had not exactly lost faith in it, but did not think the test-paper would detect a small quantity of acid so quickly as the plan he recommended in the paper under discussion, viz., rendering the bath slightly alkaline, then acidifying it, adding the acid drop by drop, and trying a plate after each addition. A comparatively large amount of acidity was only detected after a long immersion of the litmus paper.

Mr. Martin thought Mr. Leake must have used an inferior paper, and certainly not Clarke's. The solution in which litmus paper is prepared always contains free alkali, a portion of which the paper generally retains. Clarke's paper would certainly detect the presence of acid before fifteen minutes had expired.

Mr. Leake: If the test-papers are not always to be relied upon—for Mr. Martin inferred as much—he thought this was an argument in favour of his assertion rather than the contrary.

Mr. Herve never used test-paper at all, for he did not care to tamper with his bath: he used two collodions of such different natures, that when the one gave fog the other did not.

Mr. Simpson thought this a very good suggestion. Different samples of collodion, kept handy, and judiciously used, were decidedly better than tampering too frequently with the bath.

Mr. Hughes said the plan might be a very good one, if adopted for the merely practical purposes of photography, but it was not calculated to advance one's knowledge of the chemical science. Whether a photographer should study chemistry or not was a question apart; but he thought it would be as well if the operator were in a position to determine the state of his bath at any time.

Mr. Herve still thought there was much danger in tampering with the bath.

Mr. Martin believed that Mr. Hervé's half-and-half process might not always answer.

The discussion here became so conversational and discursive, and some of the remarks were made in a tone so confidentially low, that the Secretary, who was busily taking notes for this report, ventured to call attention to the fact.

The Chairman said that, having a paper still before them, he thought they might now bring this discussion to a close. After some remarks upon the bad policy of deferring discussions, which were seldom so animated when postponed as they promised to be when following immediately upon papers originating them—and pointing out the languid commencement of the present discussion, which had grown so animated at the close—went on to say: "Observation proves that we sadly want a delicate test for alkalis and acids; litmus paper is not sufficiently sensitive, and loses its power greatly if kept long. The making of litmus paper is so simple a thing, that, to ensure care in the manufacture of it, the better plan is to make it yourself, the litmus can be easily obtained, and you have merely to soak bibulous paper in the solution until it assumes a strong purple colour. To render this paper more sensitive, it is a very good plan to turn it pink with acid, and use ammonia or some other alkali to restore the colour." He regretted that none of the promised specimens had been brought forward, but attributed it to the unpropitious nature of the weather.

Mr. Clarke then read his paper *On Recent Improvements in Photographic Apparatus*, and illustrated his remarks by the exhibition of several very meritoriously contrived cameras, &c.; but without these being before the reader the observations would scarcely be comprehended.

Mr. Martin thought a description of a camera he had himself just invented, and which was about to be introduced to the photographic world by Messrs. Horne and Thornthwaite, might aptly enough follow in the wake of Mr. Clarke's paper.

Description of Martin's Universal Portrait, Landscape, and Copying Camera.

An amateur commencing the study of photography with a small lens and camera (say quarter-plate size), no sooner acquires a tolerable degree of proficiency in the art, than he becomes embarrassed by the limited capabilities of his apparatus; he longs for half or whole-plate lenses to enable him to take groups and larger sized figures; and even when supplied with these and a 9 by 7 landscape lens, he not unfrequently wishes to enlarge, reduce, or copy, and finds that even when supplied with four lenses and four cameras, he is not sufficiently well armed to meet all contingencies.

An apparatus, therefore, which, within the limit of 9 in. by 7 in., will admit of the employment of each and all of these lenses for original pictures, and for enlarging and reducing the same, becomes a desideratum, and such an one we would now offer to the notice of Photographers. It consists, primarily, of a base-board, 30 inches long and 11 inches wide, divided into three pieces and hinged together by means of broad brass hinges, so as to diffuse the bearing as much as possible, and bolted together when in use by sliding panels of mahogany, extending across the entire width of the base-board. This base-board being grooved on to its outer edges, allows the sliding portions of the camera to be moved from one end to the other, so as to alter the relation between object, lens, and image *ad infinitum*.

What may be regarded as the body of the camera is of the same construction as an ordinary expanding camera, except that it is furnished with additional apertures, and the front and back are united by means of an accordion or bellows body of suitable length.

For the purpose of illustrating its capabilities we will suppose the camera to be furnished with two landscape lenses of the respective focal lengths of 5 inches and 13 inches, and a half-plate portrait lens, whose focus is 8 inches.

Then let the enlargement required ... = e
The focus of lens... ... ... = f
Distance of focussing glass from lens ... = v
Distance of object from lens ... = u
Distance from image to object ... = a

and adopt the following formula, we shall find that our camera and lenses enable us to do almost anything within the limit of 9 by 7, or whatever size our camera may be.

$$(e + 1) \times f = v. \quad \text{And} \left(\frac{e+1}{e}\right) \times f = u$$

As an instance of the method of employing this formula, we will suppose it is desired to enlarge a picture 3½ inches square to 7 inches square, with the half-plate portrait lens, the focus of which is 8 inches. The enlargement required, or e, is then equal to 2; the focus of lens, or f, is equal to 8; then

$e + 1 = 3 \times 8 = 24 = v$, distance of focussing glass from lens.

$\frac{e+1}{e} = \frac{3}{2} = 1{\cdot}5 \times f = 12 = u$, distance of object from lens.

$v + u = a$ or $24 + 12 = 36{\cdot} = a$, distance from image to object.

Great applause was expressed as Mr. Martin resumed his seat, after a clear and brief description of this excellent invention; at the conclusion of which,

Mr. Wall called the attention of the meeting to a new and very beautiful invention not mentioned by Mr. Clarke, viz., the panoramic lens and camera, of which they had doubtless all heard—(a laugh). He thought it a most valuable introduction, and through the kindness of Mr. Cox, the optician, was enabled to bring down the lens, camera, and a very fine specimen negative (a proof from which he hoped soon to place in the Society's folio). If Mr. Leake would carefully take round the negative, he thought its examination would be very

gratifying. The only difficulty that struck him was that of printing so as to obtain an equal amount of light upon every part of the negative during this operation.

Mr. SIMPSON thought this difficulty would not exist if the printing were carried on in a diffused light, and this seemed to be the general opinion of the gentlemen present.

Mr. STATHAM suggested printing from light reflected from a curved surface.

Mr. HUGHES thought diffused light would print best.

Mr. LEAKE suggested the removal of the film by a good transfer process, after which prints could be obtained in the usual manner.

Mr. HUGHES said he had frequently tried the processes for transferring, and found them all unsatisfactory, and that the collodion when transferred grew rotten and broke to pieces after a time, however carefully attended to. He should not like to risk the destruction of a good negative by any transfer process at present in existence.

Mr. WALL remembered seeing a gentleman, the proprietor of a patent, in the studio of Mr. Clarkington, remove the films from a number of negatives and positives with perfect ease and safety.

Mr. LEAKE thought if this could be done, a copy might be obtained, and all danger of the film growing rotten avoided.

Mr. HUGHES asked Mr. Leake to tell him frankly whether, as a practical photographer, he would or could advocate the destruction of a good negative for the sake of a copy, which never equalled the original by any chance?

Mr. HERVE could support the truth of Mr. Hughes's remarks, as he had tried shellac, gutta percha, borax, and many transfer processes, without finding one satisfactory.

Mr. HUGHES described Mr. Sutton's invention as a very fine one—a beautiful idea cleverly carried out; but with all his admiration of it as a perfect piece of mechanism, he feared it would not prove of any great practical utility.

Mr. HERVE mentioned a camera of his own making, which he called universal; and expressed some disappointment at finding Mr. Clarke's paper little more than a catalogue of the more recent introductions of different makers.

Mr. HOWARD defended the paper just read, and thought it pointed out many facts which were of importance, more especially to amateurs.

Mr. Martin's new camera was much admired as an illustration of a photographic *multum in parvo*.

A new stereoscopic camera for instantaneous pictures, very compact and portable, was exhibited by H. Squire & Co., at the request of the secretary.

Mr. W. CLARKE exhibited a collection of apparatus illustrative of his paper, which excited no little interest when examined before the commencement of the business of the evening.

Mr. G. S. TEAR also exhibited a small camera and stand for stereoscopic pictures.

Votes of thanks were awarded to Mr. W. Clarke and Mr. Martin.

A paper in continuation of the "Photographic Jottings" was announced for the next meeting, on Thursday, the 15th instant, by M. Hannaford, Esq., and a jotting about photographic print washing, by Mr. A. H. Wall.

Mr. HUGHES proposed the name of Sebastian Davis for election, and the secretary at once rose, with much pleasure, to second the motion. This gentleman and Mr. Neeld were then elected members, and the meeting adjourned.

[The Society's Presentation Photograph is now ready for circulation, and may be had, or seen, upon application to the secretary, Mr. Alfred H. Wall, 90, Cannon Street West, City.]

BLACKHEATH PHOTOGRAPHIC SOCIETY.

THE twenty-second ordinary meeting of this Society was held on the evening of Monday, the 20th ult., at the Golf Club House, Blackheath Hill — the President, J. GLAISHER, Esq., F.R.S., occupying the chair.

The minutes of the last meeting having been read and confirmed,

Mr. H. T. WOOD produced a very compact and ingenious developing box for the inspection of the members, which he exhibited and described, dwelling particularly upon its internal arrangements and portability, and stating his belief that it would supersede the necessity of carrying about a tent, with the disadvantages attaching to it.

The PRESIDENT then described, at some length, the method employed at the Royal Observatory for registering the diurnal variations in the thermometer, both wet and dry bulb, by photography, and exhibited several papers on which those variations were indicated.

He stated, generally, that the method did not differ very materially from that employed in registering the diurnal magnetic variations; that is, a ray of light is reflected upon a cylinder of sensitive paper, kept revolving by a chronometer movement, and so arranged that the column of mercury in the thermometer tube, as it rises and falls, cuts off or admits the light, and thus registers its deviations in an irregular curved margin, the value of which is afterwards calculated. The importance of photography, by which such unvarying self-registering results are obtained, is here clearly recognised.

After some pleasant discussion, arising out of Mr. Glaisher's remarks, the meeting adjourned.

PHOTOGRAPHIC SOCIETY OF SCOTLAND.

THE monthly meeting of this Society was held, in Edinburgh, on Tuesday, the 14th ult., Dr. WALKER occupying the chair.

The following gentlemen were elected members: Mr. W. Henderson, Royal Terrace; Major Johnston, H. M. I. S.; and Mr. J. F. Dudgeon, merchant.

The first business brought before the meeting was the report of Mr. Horatio Ross, on the award of medals for the best pictures in the Exhibition. The Hon. Secretary, previous to reading the report, stated that Mr. Ross himself was necessarily absent, being at present at Hythe, in connection with the Volunteer movement. Mr. Ross, in the report, after alluding to the honour done him by appointing him to such a responsible office, said that when he accepted it he felt that, no matter how anxious he might be to discharge the duty with impartiality, he could not hope to give satisfaction to all.

He first directed his attention to the *landscapes*, and from the vast number of good pictures, he had great difficulty in coming to a decision. He devoted four days to the investigation, examining the pictures both by daylight and gaslight. He commenced by setting aside fifty-eight pictures which he regarded as first-class, and regretted that instead of its being in his power to award a medal to each, he had only one. He went repeatedly over this reduced list, striking out those he deemed inferior, until at last the list was reduced to three — one by Mr. Mudd, one by Mr. Maxwell Lyte, and one by Mr. Dixon Piper. These were pictures of very great excellence, and he more than ever regretted he had only one medal for this class of production. He at last awarded the medal to Mr. Mudd, not that his picture was so much superior to the other two, but that in it there were fine gradations of distance, the background and foreground being equally excellent. Had the other gentlemen selected the same subject, their pictures, he doubted not, would have been as good.

With respect to *portraits*, he could not find more than twenty that had claims to consideration, and he decided in favour of Mr. Robinson's picture, *Here they Come!* which he hoped would meet with their approval.

With regard to the Maconochie Wellwood prize he had no difficulty whatever in awarding it to Mr. Rodger, of St. Andrew's; the only doubt in the case being as to which of Mr. Rodger's pictures was best entitled to it, they were all so excellent.

Mr. Ross concluded by congratulating the Society that, from year to year, there was a marked improvement in the Exhibitions of the Society.

A MEMBER said that Mr. Ross's award had given general satisfaction, very much more so than the last year's award.

Dr. WALKER said that his own opinion might be learned from the fact, that no sooner did he see Mr. Mudd's picture in the room, on the first day of the Exhibition, than he at once purchased it.

Mr. Rodger (the only one of the successful competitors who was present) was then presented by the chairman with the Maconochie Wellwood prize, amid great applause.

Mr. RODGER, in returning thanks, said he felt highly gratified by the honour conferred on him — an honour esteemed the greater by him both from the complimentary terms in which they had spoken of his works, and from their considering them worthy of this award among so many able specimens of the photographic art. The duty of making the selection was a most difficult one; for many of the pictures displayed the highest skill in grouping, combined with manipulative dexterity. The award, therefore, of this prize by those who were justly esteemed the foremost in the photographic art, in judging of the beauties and delicacies of finish rendered in any picture, would, while it should never lessen his high appreciation of the works of merit of any professional brethren, cause him to prosecute with greater zeal the practical study of the science both so as to extend its limits and advance its onward progress towards perfection; for still much remained to be done, many new fields to be explored; and he hoped that the munificence of such worthy patrons of photographic art as Mr. Maconochie Wellwood, the donor of the prize now awarded him, would, by their praiseworthy liberality, excite a spirit not only of competition but of inquiry, which would, without fail, further the progress of the art, and be the means of producing works even of greater merit than what had this season been exhibited. To him all lovers of their pleasing art were much indebted, and, without doubt, felt grateful for his liberality. He concluded by again returning them thanks for the honour they had conferred on him.

Two pictures were exhibited, taken by the new panoramic lens.

In answer to a question, the SECRETARY said that the lens was, to a certain extent, a fluid one, and the negatives were taken on a curved plate of glass.

A MEMBER said that he could almost with certainty predict that this lens would never come into favour. In the first place the results were by no means satisfactory as to sharpness, although the views were selected apparently with a special reference to hide any defects a lens might have in the way of not giving a flat field; for in both pictures the objects in the *centre* were at a much greater distance from the camera than the sides, which were quite close at hand. The second objection was that a *curved* glass, instead of the ordinary flat plate, was required on which to take the picture.

Several other members expressed themselves as to the want of sharpness in the sides of the pictures.

The Hon. Sec. then read a paper, written by Mr. J. Mudd, of Manchester,

On the Collodio-Albumen Process.

Mr. Mudd began by expressing his regret that he was unable to be personally present on this occasion, but that he was very much gratified that it was his good fortune to gain such distinction as being entitled to one of the Society's medals; and it was an additional source of gratification to him that the picture to which had been awarded the prize was by a dry process; for although wet collodion possessed some advantages, yet, to a photographer in search of the picturesque, dry collodion, by enabling him to dispense with dark tent, dishes, &c., very far outweighed it, especially as the results were at least as good. Wet collodion, on a journey, was so troublesome, that he sometime since registered a vow that if nothing simpler could be got he would give it up altogether. He was convinced that, in adopting the collodio-albumen process, he had adopted a standard process, one on which every dependence might be placed. He first practised this process during a tour in Wales, and with complete success. Some of the views taken on that occasion were exhibited in this Society's Exhibition of 1858 and 1859.

He then described the process itself, which he said was almost identical with that originally described by M. Taupenot.

The first thing to be done was to have the plates thoroughly cleaned. Each one had his peculiar method of doing this: the one he employed was by a mixture of tripoli and spirits of wine. The plate was then coated with collodion in the usual manner, and excited in the ordinary nitrate of silver bath. It must then be washed with clean water to get rid of most of the free nitrate. Iodised albumen is then poured over its surface twice, and the plate allowed to drain, standing on one corner, for five or ten minutes. After this it is made quite hot, which has a wonderful effect in ensuring adhesion to the glass plate.

The iodised albumen consists of—

Whites of ten eggs.	
Iodide of potassium	50 grains.
Bromide of potassium	10 „
Liquor ammoniæ	100 minims.
Water	2½ ounces.

These must be well beaten together in the usual way. The plate prepared in this way will keep for years. Before using, it must again be immersed in a forty-grain aceto-nitrate bath, and then well washed with water. A plate that has been thoroughly washed will keep longer and develop cleaner than if the washing was imperfectly performed. In cool weather the plate would keep in this state for about six weeks, although he had often kept them much longer. With respect to the sensitiveness of plates so prepared, he thought it might be about five or six times slower than wet collodion, but one or two trials would decide that better than all he could say.

The development might either be conducted with pyrogallic or gallic acid. If the former, the plate is placed on a stand, a little water poured over its surface, and then a sufficient quantity of the following:—

Water	1 ounce.
Pyrogallic acid	2 grains.
Glacial acetic acid	½ drachm.

As soon as the sky or high lights begin to appear, a few drops of a ten-grain nitrate of silver solution must be added, which will have the effect of bringing out all the details. Should streaks or spots appear, they may be rubbed off without detriment to the picture, as the film is very hard. To know when a picture is properly developed is a nice point, as it often looks more intense in the dark room than when it is brought out to the light. They should not judge of its merits by the blackness of the sky, but by the details. A good picture has no part very black.

If gallic acid was used as the developer, the solution must be a saturated one. After the plate has been immersed in it for five or ten minutes, a few drops of nitrate of silver must be added occasionally until the development is completed. The fixing was effected by hyposulphite of soda.

After stating that this process was not his own, but that he had merely adopted it, he begged they would allow him to introduce this stranger among them. He concluded by stating that the camera he used was that invented by Mr. Kinnear, and he testified to its many good qualities.

Mr. J. T. Taylor said that, before any discussion took place on the subject, he would make a remark. English photographers, and Mr. Mudd among them, seemed rather inclined to give Scotchmen credit for less knowledge in photography than they really possessed. If he heard aright, Mr. Mudd spoke of *introducing* this process to their notice, whereas the Edinburgh photographers had been familiar with it since it was originally introduced by Taupenot; and vast quantities of transparencies were manufactured by this process in Edinburgh for the London and other markets.

Mr. Walker said that last year he had tried this process, but he found that the length of time required for the developing was a great drawback. Some pictures required three hours.

Mr. Orange said, that were the developer used in a tepid condition, it would reduce the time to about five minutes. He had had a great deal of experience with Taupenot's process, and for transparencies he preferred it to all others. It was very much more sensitive than the ordinary albumen process.

Mr. Taylor advocated the use of protosulphate of iron as a developer, not only for this but all the other dry processes. The certainty attendant on its use was greater than when gallic acid or pyrogallic acid was used; while the time of developing was so reduced as to make it a question of seconds, rather than of minutes or hours. Two interesting topics, he thought, might here be discussed with great advantage. First, what part was the first layer of collodion in Taupenot's process supposed to play? Was it a merely mechanical part in separating the albumen from the glass, or was it a chemical part, or both? The second was an investigation into the cause of the greater energy of iron than gallic acid as a developer.

Dr. Paterson thought that the layer of collodion had a chemical effect. This he supposed to be a union of the traces of free nitrate in the collodion with the iodide in the albumen.

Mr. Taylor said the experiments of some of the members of that best of all societies—the original Liverpool—went far to establish that the effect of the collodion film was more mechanical than chemical, for one of them had tried plain unexcited collodion with a satisfactory result; and, besides, he could scarcely agree with Dr. Paterson as to the chemical action he supposed took place, for in the washed collodion film—washed, too, with common water in which there existed chlorides and other salts—there could not be left any free nitrate of silver to combine with the iodide of the albumen. He then entered at some length on the cause of the greater energy of iron salts over pyrogallic and gallic acids in developing. The latter had, more than the former, a destructive effect on a latent image, analogous in this respect to iodine or chlorine on an impressed daguerreotype plate, or to iodide of potassium and other substances on an undeveloped collodion picture.

Mr. Dudgeon, of Cargen, said that whatever the cause might be, the fact was evident that iron developed dry plates much better than pyrogallic acid. Some time since, he took to Sweden a lot of plates prepared by Dr. Norris, and developed them all with iron. The negatives were all completely successful.

After some remarks by Mr. Burns on developing plates prepared by "Fothergill's process," and by Mr. Macnair on wort, as a preservative agent, in lieu of the raspberry syrup, treacle, beer, and other modifications of or substitutes for honey, the meeting separated.

PHOTOGRAPHIC SOCIETY OF IRELAND.

The monthly meeting of this society was held on Friday evening last, the 24th ult., at the Royal Dublin Society's House—Frederick Sanders, Esq., in the chair.

The minutes of the previous meeting having been read and confirmed, H. T. Vickers, Esq., Honorary Secretary, read a paper, by E. K. Tenison, Esq., J.P., D.L., County Roscommon, descriptive of a paper process. Mr. Vickers read a communication from Mr. Tenison, regretting his inability to attend the meeting of the society owing to his detention on important business in London.

Mr. Tenison's observations were, in effect, that he had tried almost every process of photography, from its first introduction by Daguerre on the silvered plate, up to the present time, on both waxed and unwaxed paper, together with the albumen and collodion processes on glass,—having been much devoted to each in its turn; but, having almost given up the science altogether, he might now be allowed to express an opinion on the merits and advantage of each system without being considered prejudiced in favour of any. The extreme minuteness of definition in the daguerreotype system could not be denied, nor could it be excelled even by the collodion positive picture on glass. The process, however, had its disadvantages, which did not require recapitulation. In point of definition the albumen process seemed to come next, to which process, he thought, justice had not yet been done. The process was certainly slow compared with the collodion; but the albumenised plate retained its sensibility so long, that it fully equalled in point of convenience the dry collodion. Mr. Maxwell Lyte was the only successful manipulator of the dry process whom he had ever seen, and his results he considered beautiful. He had seen Mr. Lyte travelling with his dry sensitised plates, and never knew of a failure. Still, however, there was great inconvenience from carrying so much glass. The advantage of the paper process to a travelling photogropher was immense, provided it was limited to architectural subjects and landscape scenery. Figures could rarely be introduced, except as Count O. Aguado did, who carried with him various lay figures of both sexes, which, after being dressed in the costume of the country, he placed in the most prominent positions to suit his pictures. It was true the development of a paper negative was slow, but that prolonged the pleasure to an amateur. There was little danger of over-exposing a waxed-paper negative, whereas, with a collodion, a minute more or less might spoil the result; besides, one hundred paper negatives, sixteen by ten, could be easily carried in a portfolio weighing less than two glass plates of the same size. He thought that each paper process or formula had a paper more or less adapted to it. The Fox Talbot process he generally found best on old English paper; whilst the French and German papers probably suited best Le Gray's process, having been previously waxed; but Baldus's plan succeeded best with a papier Saxe. He found Le Gray's printed formula excellent. From him he learned the waxed-paper process, and worked with his paper successfully for several years. He afterwards became a pupil of Baldus, and a convert to the calotype or unwaxed method of iodising. This process was perhaps rather more troublesome

than the other, as the negative picture, when fixed with hypo, &c., should be well waxed before it could be used in the pressure frame for printing. This process he found more generally successful, and produced cleaner negatives and darker skies. He did not think that climate or temperature much affected the methods of Le Gray or Baldus, whereas the collodion amateur constantly found his bath out of order without any apparent cause; indeed, so far as his experience went, he had found collodion capricious and uncertain in its results. He had, according to the Baldus mode, iodised in a few days sufficient paper to serve him a year or two, and never found it to deteriorate when kept dry. If a paper negative, from exposure or over-development, became too dark for printing, it could easily be rendered clearer by a chemical process which had been adopted by French photographers. The same chemical action would cleanse a negative if injured by the nitrate of silver from frequent contact with positive sensitised paper. Sir William Newton, he believed, worked the calotype process, and sensitised with a glass rod. He had tried that for some time, but found it far more difficult than either of the other processes which he had mentioned. He recommended all beginners to adopt one system, and not to attempt various methods. Each process had its advantages and disadvantages, but each was capable of producing good results. There was no more difficulty in manipulating a piece of paper 16 inches by 12 than there would be in manipulating one half that size. He strongly recommended Baldus's system, because of its simplicity and general success. In his photographic excursions the whole of his apparatus, except a few glass bottles for solutions, was entirely of gutta percha, thus avoiding all danger of breakage.

The CHAIRMAN remarked that, of course, there was a great deal to be said in favour of paper, as compared with glass, on account of its portability.

Mr. VICKERS said it was very much to be regretted that they had not been favoured with more detail as to the exact manipulation. However, it was right to state that it was not Mr. Tenison's intention to leave them in the dark, as he originally hoped to have read the paper himself—to have explained how the process was to be carried out, and to have exhibited the manipulation. However, on a future occasion they might expect Mr. Tenison's explanation.

Mr. BEATTY then exhibited a number of photographic engravings, according to the Fox Talbot method, and produced the negative and copperplate of a programme of the Royal Dublin Society's meetings for the evening. In his paper, explanatory of the process, Mr. Beatty remarked that Mr. Fox Talbot's productions possessed almost all that could be desired in minuteness of detail, depth of shadow, and graduations of half-tone, which had never been approached by any other process hitherto adopted. They realised the aspirations of the enthusiastic photographer, by affording permanent pictures of the fleeting images of nature, reproduced by means of the printing press. Having referred to Nièpce's plans, Mr. Beatty characterised them as simple, and gave him the credit of being the first to fix, not only a direct positive photograph, but also to secure on metal and glass plates the images of the camera obscura. The simplicity of his plans arose from the tendency of light to dry certain varnishes, and to make them insoluble. When so dried, the portions not acted on by the action of light washed away by certain solvents. Asphaltum was employed with oil of lavender to produce a varnish with which the plates were coated; when partially dry, they were exposed to the light with an engraving superimposed, or they were placed in the foci of a camera obscura, and after a time a photographic image was obtained on the varnished plates. This image was not visible, and the plate had to be subjected to the solvent action of a mixed liquid, composed of one part of oil of lavender and ten parts of mineral naphtha. On immersion in this fluid, wherever the light acted, the varnish became insoluble, and in a certain degree proportionate to the intensity of the light. The shadows of the picture were now represented by the parts of the white metal or glass laid bare by washing with the solvent: the lights were given by the film of varnish which had been hardened by the action of light, and which had been left untouched by the solvent. The plate was etched by the ordinary method used by engravers, by the application of an acid; while the shadows and demi-tints, partially or wholly denuded of the varnish, were "bitten" into the plate by the acid. On washing the plate and removing the varnish, an etching was produced, capable of being charged with printing ink, from which impressions could be taken in the printing-press. The method with which Mr. Fox Talbot used to produce engravings on steel and copper was simple, but required great care in the manipulation. A plate of polished steel or copper might be used; the plate should be perfectly clean, and coated with a solution of gelatine and bichromate of potass; it should then be dried over a spirit lamp; when cold, a photographic glass was to be laid on the coated plate, and placed for a time in diffused daylight, in order that it might pass through the transparent portions of the picture into the gelatinised surface. Experience could only make known the time which the plate should be allowed to remain in this position; it was then to be placed in a dark room where it had been previously coated, and, when breathed upon, the subject which covered the plate would appear in all its detail. Mr. Talbot, instead of washing the plate, sifted over its surface some finely powdered gum copal very thinly and evenly, so as to form an engraver's aquatint ground: he then heated the plate over a spirit lamp, to melt the coating which would adhere to it in finely divided particles; and then applied, with a camel-hair brush, perchloride of iron, slightly impregnated with water, graduated to the proper strength, which could only be ascertained by experience.

Mr. BEATTY was warmly applauded at the conclusion of his explanation of the process.

Mr. VICKERS said it was right to mention that the plates had never been touched by a graver.

The CHAIRMAN inquired the length of time necessary for exposure?

Mr. BEATTY replied that in diffused daylight it required an exposure of about three hours, but in the sunlight it would take only about so many minutes: he preferred the slow action.

The meeting was then adjourned.

LIVERPOOL PHOTOGRAPHIC CLUB.

THE usual monthly meeting of the above was held at the house of Mr. Bell, on Tuesday, the 14th ult. There was a full attendance of members and some visitors.

Mr. BERRY exhibited an extremely fine proof of *Conway Castle*, from a negative two feet square. This negative, upon one of Hill Norris's plates prepared expressly for the operator, was very clear in detail, the tone of an even character, and the shadows, although deep, sufficiently transparent. A further peculiarity connected with this picture, was the fact that it was taken with a lens (four inches and a-half in diameter and about three feet focus) which had been sent by a dealer of great repute to a very good customer. He had returned it, saying it was not capable of covering a surface of five inches with accuracy; whereas the clearness and sharpness of outline were remarkable in this vast print, up to its extreme edges: thus the learned differ. A further difference of opinion was exemplified when

Mr. COREY showed two negatives on waxed paper, taken during the late severe weather, and commented upon their imperfect transparency, although prepared by the iodising solution containing cadmium so much recommended by Mr. Long, who asserts that "you thereby get rid of the granular appearance" so offensive in most waxed paper. These negatives were bold and energetic, clear in outline, and full of definition, but many of the shadows were woolly. He was disposed to think this arose from bad glacial acetic acid. In this Mr. Cook fully concurred; whereas Mr. Bell, who has had much experience, laid the fault to the paper, with a great show of probability, for it was a specimen of Canson's, made many years ago, and waxed nearly as long. On the other hand, Mr. Berry attributed the defect to a want of sufficiency of silver in the sensitising solution, whereby an equal balance had not been preserved in forming the iodide. Mr. Hooper, in a paper read at the Chorlton Society, had strongly insisted on the necessity for this.

Mr. FORREST exhibited some extremely fine stereoscopic prints, sent to him by Messrs. Anthony, of New York. These were taken in the most crowded thoroughfares, and gave a very vivid idea of the busy throng. They were remarkable for having been taken by a process instantaneous almost to a miracle; for though persons and vehicles were evidently in rapid motion, not a single figure was blurred or uneven in the outline; nay more, the steamers crossing from New York to Brooklyn had every individual ripple in their wake crisp and distinct as in nature.

Mr. BELL also exhibited some very large views of the mighty waters of Niagara. These were very choice, and gave the beholder a grand idea of the horse-shoe form of the Falls.

Mr. FORREST, having been urged by several friends to correct many errors which had crept into print of late on the subject of glass manufacture, now proceeded to read the first of a series of papers on the subject of glass-making generally, and for photographic purposes especially. [See page 64.]

After a very social evening the members separated, looking forward with pleasure to the next meeting at Mr. Forrest's.

CHORLTON PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of this association was held on Tuesday, the 8th ult. Mr. JOHN FAWCETT occupied the chair.

After some preliminary business, Mr. WARDLEY called the attention of the meeting to the many formulæ recently brought forward for the collodio-albumen process, and noticed how slight was the difference in any of them from the original process as introduced by M. Taupenot. With the consent of the meeting, and in order to discuss this subject fully, he proposed to occupy some of the time of the next meeting by reading M. Taupenot's original paper. He made this announcement in order that gentlemen might be prepared.

Mr. HOOPER exhibited to the meeting an actinometer, made according to the formula of Dr. Woods, of Parsonstown. He had found it very sensitive to light, but it was also affected by heat; and he then explained how that difficulty might be overcome without recourse to a thermometer.

This actinometer was thought to be a very simple and useful instrument for the photographer, and the explanation and discussion of its merits being interesting to the members, it occupied the meeting a considerable time.

A MEMBER inquired if Mr. Griffiths was prepared to address the meeting on the enlarging process he had before mentioned to the Society. He made this inquiry because he had heard of a picture, five inches by four, being enlarged to sixteen inches by fourteen, perfectly sharp, and he was anxious to know something more on this subject.

Mr. GRIFFITHS, in reply, said that he was ready to do so, but should prefer waiting until the next meeting, when he expected to be enabled to show specimens.

Mr. Rogerson thought that from the efficient manner in which Mr. Hooper had treated the subject of the actinometer, he deserved the thanks of the Society, which he moved should be given to that gentleman.

This was seconded and carried by acclamation.

A vote of thanks having been accorded to the Chairman, the meeting concluded.

CALEDONIAN PHOTOGRAPHIC CLUB.

This Club met on Friday evening, the 17th ult., in the apartments of Mr. Steele, who was host on the occasion, and, according to custom, occupied the chair.

The Secretary having read the minutes of the last meeting, Mr. Montaigne said:—A few days ago, on arriving here from a journey from Ireland, I saw in The British Journal of Photography a report of the proceedings of our last meeting, and I must say, without meaning any offence to our Secretary, I never saw a worse report in my life. By no means would I insinuate that anything garbled or untrue exists in the report, but I am dissatisfied at the idea of a long and interesting meeting, replete with debate, being crushed up in such a nutshell report as the one in question. If our transactions are worthy of publication at all, they are surely worthy of being given in their entirety.

Mr. Wilson: For want of experience I just adopt the method usually employed in procuring reports of some other societies, such, for instance, as our elder brother, the Photographic Society of Scotland: I send for publication only so much as I deem expedient should meet the public eye, and in order to ensure accuracy in any remarks made, which I consider worthy of publication, I usually request each speaker to furnish me with a written copy of what he said.

Mr. Montaigne: I am well aware that such has been the case; but in order that some Society should set the example of putting a stop to a system which is so unfair to the photographic reading public, I propose we secure in future the services of a professional reporter.

After further discussion on this subject, it was agreed that the Secretary should communicate either with Mr. Kinnear, Dr. Diamond, or Mr. Shadbolt, with a view of getting the benefit of some of those gentlemen's experience in furnishing reports.

Mr. M'Adam then read a paper *On Printing Glass Transparencies.*

[The MS. of this paper having only come to hand just as we were going to press, it must unavoidably lie over for a fortnight, together with the discussion that followed on the subject.]

The thanks of the meeting were cordially awarded to Mr. M'Adam.

A conversation ensued on the subject of professional photography in Edinburgh.

Mr. Brown said that, if he had been rightly informed, Princes Street would soon be one great photographic establishment from end to end, as he believed that several photographers of standing were about migrating thither:—Tunny, of Clerk Street; Rodgers, of St. Andrew's; Duboscq, of Paris; together with two eminent London photographers, whose names he was not at liberty to mention—all contemplated removing there at Whitsuntide. Ross and Thompson he also believed were leaving their present place in favour of more suitable premises.

The Chairman said that he knew for a fact that every suitable place in North and South Bridges, and other important streets, had been eagerly sought after by photographers; and from the number of new ones about to be established in the minor streets, together with a great anticipated addition to the already numerous host of "travelling artists," he had no doubt that the lieges in this part of the kingdom would, in the ensuing summer, get their portraits taken at a great reduction on the prices of last year, which, in the Canongate, were threepence each, including a gilt frame.

The remainder of the transactions will appear with Mr. M'Adam's paper in our next.

Manchester Photographic Society.—In our report of the last meeting of this society, it was stated that Mr. Cottam contributed to the society's folio a print from a negative taken by the panoramic lens; the donor requests us to mention that the proof in question was a developed print, produced by Mr. Sutton from a negative as quoted.

Exhibition.

LONDON PHOTOGRAPHIC SOCIETY'S EXHIBITION.

[Second Notice.]

Press of matter precluded the possibility of our continuing this notice in our last. On reference to our catalogue, we perceive that our next memorandum relates to the contributions of Mr. Lyndon Smith, of Leeds, a gentleman whose name is well known as an ardent photographer, but with whose works we have not hitherto been familiar. In glancing at Nos. 23, *Valley of the Wharfe, Early Morning*, and 47, *Study in the Valley of Desolation*, it is impossible to be otherwise than struck with the fact, that the producer must possess a strong appreciation for the beautiful and artistic, and yet, strange to say, we have rarely felt more disappointed than after examining the two specimens we have named. There is a peculiar *spottiness* and confusion about them that is very unsatisfactory, and the exaggerated effect of attempted atmosphere is carried to an extent that causes one to tremble on account of the anticipated attack of rheumatism and bronchitis from being exposed to such a dense mass of vapour. These failings are the more provoking, because they are not only evidently under the artist's control, but it is manifest that he is capable of better things, as witness for instance his *View of Knaresborough* (No. 67), which is soft, clear, and verging on the very opposite extreme of manipulative dexterity, being only so far short of failing from over-exposure as to be almost liable to a charge of want of vigour; while in the two previously mentioned the details in the foreground are unpleasantly hard. This (No. 67) is, however, a very charming production, and forms a beautiful illustration of our quiet English landscape pictures. It is a great pity that one who evidently possesses in an eminent degree the artistic element should suffer himself to be led astray by the conventional mannerisms which we have noticed. We have been told that the aqueous-looking atmosphere does not exist in the negative, but that it is an effect produced in the printing by what has been decried as a "trick." We do not perceive, by the way, the justice of such a designation. If it be a "trick" it is a clever one, though in our opinion in the instances cited carried to an unreasonable and detrimental extreme; with somewhat less of straining after effect, the operation, whatever it be, might be very probably beneficially applied.

Mr. Dixon Piper contributes many carefully-executed subjects, amongst which we admire No. 479, *The Old Curiosity Shop at Bury St. Edmunds*—an illustration that forcibly calls to mind the work of that name by Mr. Charles Dickens: we almost expect to see the figure of "Little Nell" emerge from the shop door. Another very excellent production by this photographer is No. 178, *A Cottage, near Ipswich*, which is very cleverly treated, though perhaps there is in the cottage itself rather too marked a patch of white in the composition, which would be improved if this part were a trifle deeper in tone.

Mr. J. Spode has a keen eye for the picturesque, and contributes many very exquisite productions. No. 435, *Lilleshall Abbey, Salop*, though a little spotty, is very artistic in treatment. No. 445, *Goodrich Castle*, by the same gentleman, and No. 457, *Netley Abbey*, are perhaps some of his best.

Mr. Vernon Heath has produced some very nice pictures. No. 452, *The Cottage Porch*, is especially worthy of commendation.

Mr. Victor A. Prout has very successfully rendered a number of interiors, many of them subjects in Westminster Abbey, of which Nos. 254, *The Cloisters*, and 277, *The Tomb of Edward III.*, may be taken as fair samples.

In noticing Mr. Fenton's works we omitted to mention one with which we were specially pleased: No. 304, *Altar of the Sodality Chapel, Stonyhurst.*

Mr. A. J. Melhuish, of Blackheath, furnishes many interesting scenes, amongst which there is one that we have often seen pourtrayed before, but never with anything like success until now: we allude to No. 330, *Black Gang Chine*, in the Isle of Wight. The fact is that it is a very difficult subject to convert into a *pleasing* picture.

Messrs. Bisson Frères, in addition to other subjects, exhibit a very effective *Panoramic View of Mont Blanc.*

M. Gabriel de Rumine unfortunately sent in his contribution at so late a period that there was not a particle of space left uncovered on the walls or screens when they arrived, and they are consequently hung at the back of the screens, but in so bad a light that we could not properly see them either by night or day.

A similar observation applies to some American photographs, which, like the last named, are not mentioned in the catalogue; but they have the advantage of not being hung at all, but simply stand upon the seat and rest against the screen, so that visitors with an inquiring turn of mind can examine them by taking them in their hands. They are well worthy of examination, and represent scenes materially differing with those with which most people on this side of the Atlantic are familiar.

The screen next the door is devoted principally to stereoscopic subjects, of which there are many by Mr. Russell Sedgfield that have been already noticed in our columns. Mr. Bedford appears also as a producer of stereographs, but we do not think him nearly so successful in this branch of photography as in his usual walk, most of the specimens exhibited being in our opinion far too hard. There is a frame standing on one of the seats containing stereographs by Mr. Woodward, of Nottingham, which, though not nearly so natty and sightly in the mounting as many others that

are better displayed, possess intrinsic merits far superior, and will repay examination.

We now come to a point in which we take peculiar interest—a comparison of the results produced by several of the dry processes; of which we have in the present collection a very fair exposition. Our friend, Mr. Rosling, as usual shines in his manipulation of collodio-albumen plates by the original process of M. Taupenot; and in several of his frames of four subjects, one or more by the ordinary moist collodion may be noticed, as introduced for comparison. Nos. 4, 19, and 71 are excellent illustrations in Mr. Rosling's happiest manner. The printing of Mr. Rosling's specimens is also super-excellent.

Mr. James Mudd, of Manchester, is also a disciple of the collodio-albumen process, and an eminently successful one. His picture, which gained the prize medal of the Scotch Society, we have already noticed His *Moat and Bridge, Chorley Hall, Cheshire* (No. 10), is scarcely less successful, as also No. 224, *View from the Cloister Window, Fountains Abbey*, and No. 424, *View in Scardale, Lancashire.* Those who talk of the *hardness* of collodio-albumen productions should examine those we have just cited, and we have no hesitation in declaring that they must necessarily admit that hardness is not a failing that need ever be incurred when working by this process.

Of Mr. S. Bourne's specimens (No. 50), by the Fothergill process, we have already spoken in favourable terms.

Mr. Sykes Ward, with his modification of the collodio-albumen, is not so successful, most of his pictures exhibiting the peculiar brain-like markings in the skies of which some operators complain. One specimen, however, his *View on the Wharfe* (No. 179), is good, and free from the defect alluded to.

Dr. Hill Norris's process finds favourable illustrators in the persons of Mr. Melhuish and Mr. A. R. Hamilton (Nos. 113, 329, 347, 385), &c.

The oxymel process has its advocates in Mr. Penny (Nos. 384 and 420), Mr. Barber (No. 410), Mr. Melhuish (No. 346), Mr. Baynham Jones (No. 112), &c.

It is, however, to the exertions of a lady, Mrs. Verschoyle, that we are indebted for illustrations of the largest number of preservative processes by any one operator, as shown in Nos. 72, 314, 428, &c., which include proofs from negatives by the honey, dry collodion, and collodio-albumen processes, fairly contrasted.

The conclusion at which we arrive relative to the results obtainable by the various preservative processes, is—that when properly worked each one is capable of yielding first-rate productions, and that the choice of any one of them should be rather dependent upon the peculiar convenience of each operator, than upon any fancied superiority as regards excellence inherent in any one of them.

Practical Instructions on Coloring Photographs.

By Alfred H. Wall.

CHAPTER VI. *(Continued.)*

DRAPERY.

If the head has been properly lighted you will find great roundness produced by the folds of the drapery and its gradations of shadow, which it must be your especial care to preserve. Remember to graduate the strength of your high lights and preserve the relative intensity of the shadows, deeper shadows being, of course, associated with the fainter high lights, except where powerful reflected lights moderate their intensity. Keep the more prominent folds lightest, that the effect of retiring surfaces may be increased; and if the number of folds appears destructive of breadth, judiciously omit such as play no important part in the expression of form, or texture, and are situated near the larger mass of light. Finding that the particular quality and character of drapery is indicated by certain peculiarities in the folds, be careful not to destroy their effect. You will find small narrow folds have a tendency to angularity, and larger folds to curves; do not, therefore, give the one species a characteristic peculiarity belonging to the other. The specific quality of surface being (as I have said) indicated by peculiar lights and shadows, and by characteristic folds, you will perceive the danger of making any alterations in a good photograph, in which all these qualities are displayed in such wonderful perfection. However, to assist you in recognising (and consequently preserving*) these important points, I will just note down a few of their peculiarities.

* The reader will have noticed the constant repetition of this word, purposely introduced to impress upon his mind a principle which should never be out of the colourist's view. *Carefully preserve* may indeed be here called my motto.

CLOTH.

The folds in cloth (being a rather thick and soft material) have much beauty, are broad, rather flat, and greatly varied in their character. The lights, unless where the surface is very glossy, are not strong, will be easily discovered upon the most prominent parts, and are very soft in their character. Shining lights will be found tracing the channels formed in the hollows between the folds, or in their breaks; which lights are more abrupt than high lights, although very nearly as strong. The reflected lights are weak. Without advocating a servile imitation of various stuffs, I certainly think each should be so represented as to leave no doubt in the spectator's mind as to what the drapery is really composed of.

SATIN.

The folds of this material are somewhat conical and are frequently broken into crescent-shaped terminations in consequence of its stiffness. Its reflected lights are strong, its high lights brilliant and well marked, and its shadows seldom very intense, in conquence of the presence of reflected lights of a more than usual strength and number. The masses of light and shadow are generally very picturesque, and may be judiciously strengthened by a proper gradation of the lights, shadows, and reflections, from the lighted to the shadowed portions.

VELVET,

being seldom photographed well, demands more attention than other surfaces. It is very picturesque when well managed, and is so strikingly different from all other materials as to be easily recognised. The prominent parts are darkest, and the lights are found near the edges of the folds, or receding parts, and wherever the undulations of the surface cause the pile to catch a stronger light. Velvet being very thick and soft, the folds are massive and rounded in their contours and the breaks are more gradual.

FUR

is very perfectly displayed in good photographs, and should not be destroyed in the colouring. Its character resembles closely that of velvet, and the lights are discoverable *near*, but not so *close to*, the edges, because the surface of hair is more raised and open than the pile of the velvet; for the same reason its edges are more transparent, and blend imperceptibly with the surface upon which it lies. The prominent parts of fur are dark, its reflected lights strong, and its folds large.

I do not think I need offer any further remarks upon the subject of drapery here, as you are sure to be correct if you adhere closely to the photograph, and duly consider the nature of the surface to be rendered, whether it be rough, smooth, or polished. And thus end my remarks upon "touching" photographs.

The author of the preceding paper, in order to render his communications of greater practical value, has kindly undertaken to criticise the work of students in colouring, and to give them advice through the medium of these pages; for which purpose specimens may be sent, with a stamped and directed envelope *for their return, to* A. H. Wall, Esq., 11, The Terrace, Walworth.

An Amateur (Rochdale).—The backgrounds you describe may be mere flat washes of body colour floated on with a large full brush, or they may be procured in the following simple and effective way:—Take crayon in the powder, mix the tint or tints required, and rub them in with your finger, adding, blending, and evening up until the result you desire is obtained. With regard to the beauty of such clean opaque grounds, you and I do not agree, although (per desire, or to meet the demands of undue haste) I sometimes finish backgrounds in the way described. If the artist near you uses the chalk-process, you will find no difficulty in emulating him; but it is as well to put in the background first, as there is some danger of rubbing the chalk over portions of the figure which would be of less consequence before, than after colouring.

G. R.—Varnish is generally adopted for the purpose; but there is another plan:—Coat the surface with rather strong gum-water, apply the powder colours, and afterwards wet the back of your picture until the gum dissolves and fixes the colours. Isinglass dissolved in gin is sometimes used for the same purpose, just as you would the varnish; and I have heard of a solution of white wax being applied in the same way. The whites of dry colours are generally prepared from calcareous earths. Flake white would never do, as it always darkens if unprotected by oil or varnish. The contractile influence of varnish upon powder colours, is the origin of the effect you describe. Try a weak solution of resin in spirits of wine. I cannot enter more fully into the subject upon the ground of fairness to others.

Foreign Correspondence.

Paris, February 22, 1860.

The first meeting of our Photographic Society for the present year was remarkable for an incident which will probably form an era in photography. Three observers, situate at a great distance from each other, united in calling attention to a peculiarity in the collodion process which hitherto had passed unnoticed, viz., the possibility of obtaining at will, from a collodioned plate, either a positive or a negative picture. The first of these observers, Count Schouvaloff, describes his process as follows:—The collodion must be very feebly iodised, and of a kind that will yield a very weak

image. The exposure must be very short, and followed by a development with pyrogallic acid so rapid that it can scarcely be imagined or suspected that the negative image is in the latent state; the plate is then freely washed in a stream of water, so as to entirely remove the developing solution; then a small quantity of an old nitrate bath is poured over the washed plate, and after it has remained a sufficient time it is poured off, and the plate shaken so as to remove streaks, ensure a uniform surface, and as thin as possible; the plate is then set to drain, placed in a horizontal position, and the developing renewed with pyrogallic acid, which is allowed to remain some time in contact with the surface. If the operation has been well performed, and particularly if the original coating of collodion is perfectly uniform, the developed picture will no longer be a negative, as it would have been if the first development had been completed, but a positive picture, in which the opaque parts correspond to the opaque portions of the model, and the transparent parts to the lights, &c., and which may be toned or intensified by means of chloride of gold and other analogous agents. The Count adds:—"I remember to have read somewhere that effects of this kind are obtained by exposing the collodion to daylight during development. But I am quite certain that in my experiments light had nothing to do with the result, since I took the greatest precautions in this respect without any difference."

M. Poitevin, another photographer, whose name must be well known to you in connexion with photo-lithography, states the following as the result of his experiments:—1st, A layer of iodide of silver, in presence of nitrate of silver, and exposed to the light, is blackened by pyrogallic acid. 2nd, The same exposed layer, washed to remove the nitrate of silver, and covered in the dark with a solution of iodide of potassium, again washed, and then covered with a solution of nitrate of silver, is also blackened by pyrogallic acid. 3rd, The very brief action of light upon the preceding layer, previously exposed and iodised, removes from it the property of being blackened by pyrogallic acid. That understood, proceed as follows:—Iodise the plate with a weak iodising solution, and sensitise in the usual manner; expose the sensitised plate to direct light for a few seconds; it does not change in appearance; remove the nitrate by copious washing in water; cover the impressed surface, in the dark, with a solution of iodide of potassium, of four grains per hundred; if the surface has become dry, substitute the alcoholic for the aqueous solution of this salt; it is on the layer thus prepared, in which the nitrate of silver is replaced by the iodide of potassium, and which has in consequence lost the property of being blackened by pyrogallic acid, that the light is made to act. When placed in the camera to receive a direct or positive image, the exposure must be three times as long as in an ordinary negative picture; after exposure, the plate is washed in distilled water to remove the excess of iodide of potassium; it is then immersed in a weak bath of nitrate of silver, and treated with acidulated pyrogallic acid, which only blackens the parts *not* acted upon by light; we thus obtain a picture in which the *chiaroscuro* is the exact counterpart of nature. The sensitised layer covered with iodide may be kept unimpaired some hours before exposure, but as the action of the iodide of potassium takes place by degrees even in the dark it must not be kept too long. M. Poitevin added, that he substitutes lactic acid for acetic acid in the preparation of the solution of pyrogallic acid. He sees in his process a means of obtaining direct transparent positives, by which proofs in ordinary ink may be printed according to a process he has invented. At the meeting he exhibited some stereoscopic positives, which, although taken by an inexperienced hand, were as good as the positives on albumenised glass, produced by M. Ferrier, but so difficult to obtain by his process.

Much uneasiness is caused to photographers by the law treating photographs as engravings and lithographs, and requiring that specimens should be deposited with the authorities, as in the case of other works of art. It seems to be impossible to avoid this extension of the law, but its application will be attended with many difficulties, for the majority of private portraits taken cannot be considered as publications, and it will be scarcely possible to bring them under that category.

Our photographers are bringing forward much evidence to show that Woodward's solar camera is not new. M. Quinet claimed the priority in adopting the principle upon which that instrument is constructed. Many years ago he also claimed the invention of the orthoscopic lens; but M. Bertsch reminded the society that this form of combination was in use before the date claimed by M. Quinet—that he and M. Le Gray had experimented with it without thinking it necessary to claim priority of invention. M. Quinet patented in 1852 an apparatus answering the purpose of Woodward's solar camera. This apparatus is vertical: it is composed of a parabolic reflector projecting light from the sky, or from a lamp, upon the glass plate, and of an optical combination, intended to throw an enlarged image of the original upon a sensitive plate.

M. Bertsch remarked that there was nothing new either in M. Quinet's or Mr. Woodward's mode of lighting, nor in the principle or construction of their cameras. The solar microscope, invented in 1738 by Nathaniel Lieberkuhn, of Berlin, and improved by Cuff, Appinus, Baker, and Chevalier, differed from these *new* apparatus only in dimensions: the amplifying apparatus and material arrangement are the same in each. As to its applications, the portraits exhibited by M. Tournachon, jun., and those of Dr. Gontier, presented to the *Académie* in 1849, established the fact that they are by no means recent.

Correspondence.

ASSAYING SILVER AND GOLD RESIDUES.

To the Editor.

Sir,—Since writing to you on the subject of economising alkaline chloride of gold toning baths, I have been asked whether the reduced material might be reconverted into chloride of gold without the trouble of fusing it into a button? It would undoubtedly be easy to purify it by simply pulverising, and digesting for half an hour or so in commercial muriatic acid diluted with an equal bulk of water. This hydrochloric acid is so cheap a substance, that it is not necessary for me to fix the minimum quantity which would suffice. The best plan would be to add enough in the first instance to cover the powder to the depth of half an inch, and after a quarter of an hour's digestion to pour it off and put in a fresh quantity. The gold is insoluble in hydrochloric acid; but the whole of the carbonate and oxide of iron dissolves, forming a yellow liquid, which is a mixture of proto and perchloride of iron. When the hydrochloric acid last added ceases to assume a strong yellow colour, the iron is all separated, and it remains only to mix nitric acid and hydrochloric acid in the proportions for *aqua regia*, and to dissolve the gold by a gentle heat. This part of the process has been sufficiently described in the back numbers of your Journal—the mode of separating the iron from the gold being the point to which the question referred.

A correspondent has sent to me packets containing dried sulphide of silver, and also ashes from sensitive paper. Of the former he has collected a large quantity, many pounds in weight, by systematically precipitating his old fixing baths with sulphide of potassium, supplied to him for that purpose by the operative chemist. I see it stated in a contemporary publication, that in France they deal with dried sulphide of silver by simply deflagrating it with nitrate of potash. This process certainly answers the purpose, and is so easily performed that it might be done in the dining room, or at all events over the kitchen fire. All that is necessary is to rub up the black sulphide in a Wedgwood mortar, with twice its weight of nitre, and having placed a clay crucible on the hot coals, to throw the powder into it, a little at a time. It is not necessary that the crucible should be red hot, since when the action has once been started the heat is maintained by the deflagration. Free sulphur, if present, burns away with a blue flame, and the sulphur contained in the sulphide is oxidised by the nitre into sulphuric acid, and remains combined with potash in the form of sulphate. It might be anticipated that the silver would be left behind as an oxide of silver; but the affinity of silver for oxygen is so slight, that no formation of this compound takes place at a high temperature, and the reduction is complete. When the combustion is over, the crucible is allowed to cool, and boiling water is then poured into it, which dissolves out all the potash salts, and leaves a fine network of metallic silver. This may be afterwards run into a button by sufficiently raising the heat.

By operating as above described upon one hundred grains of the black powder sent to me, I obtained forty-eight grains of metal; and on dissolving the button in pure dilute nitric acid a powder remained, which after ignition weighed 1·3 grains, and consisted of pure gold. The presence of so large a quantity of gold in the silver is explained by the fact that the precipitated sulphide of silver was obtained from hyposulphite solution which had been used both for toning and fixing, according to the old method. And I may take this opportunity of mentioning that when such is the case, it is important to add only just enough of the sulphide of potassium to throw down the whole of the silver; since, if any excess be permitted, the gold will be taken up again in the form of a double sulphide of gold and potassium.

Your readers will observe that the quantity of real silver in the black powder, viz., 48 per cent., was less than might have been anticipated. Pure sulphide of silver contains at least 87 per cent. of metal: so that it is probable that the residue was not perfectly dry, and also that it contained uncombined sulphur, and organic matter.

The ashes of the paper were treated in the same manner as the sulphide; but it occurred to me at first that a little carbonate of potash or soda would be needed as a flux for the chloride of silver. Experiment showed, however, that nothing of the sort was necessary, and that deflagration with an equal weight of nitre left the silver in a metallic form:

in fact, as the ashes of the paper contained unburned carbon, carbonate of potash was formed during the deflagration. The metallic silver obtained from one hundred grains of the ashes weighed rather more than sixty-six grains.—I am, yours, &c.,

King's College, Feb. 22, 1860. F. HARDWICH.

ROCK INSCRIPTIONS WANTED!

To the Editor.

Sir,—In the concluding paragraph of No. 13 of the "Notes of a Photographic Tour in the Holy Land," the dashing author looks forward with anxious interest to the next batch of Photographic Journals.

I beg to suggest that the publisher should inclose a *Bible* in the parcel, and draw the attention of the sprightly author, and his friend "John," to the seventeenth chapter of the First Book of Kings, in connexion with page 50 of the Journal for February 15th.

Although he says very little of the pictures that he has taken, they will, no doubt, be exhibited on his return; and I hope to see one of that most interesting relic, the barrel of meal, or the cruse of oil, which Elijah GAVE to the widow of Zarephath. The history does not make mention of the caravan of camels, loaded with flour and oil, which accompanied the prophet from the brook Cherith; but your lively friend may have met with some traditionary account of, perhaps, rock inscription relating the circumstance.

A photograph of such an inscription would be invaluable. It would not merely furnish a *facsimilé* for the Journal, but could not fail to draw in its train an incalculable amount of learned correspondence.

I am, yours, &c.,

A CONSTANT READER OF YOUR EXCELLENT JOURNAL.

P.S.—The tourist should have been furnished with one of Mr. Skaif's pistol cameras, which would have served quite as well as a revolver, to frighten robbers; and we should then have had an *authentic* picture of the chief, taken in the act of falling from his horse at the sight of a pistol barrel: the countenance and general expression would have been a study for painters.

VARYING THE FOCUS OF A PORTRAIT COMBINATION.

To the Editor.

Sir,—Although but little acquainted with optical matters, I read with much interest Mr. Grubb's excellent paper "On the Optical Centre" of compound lenses, in No. 112 of your Journal, and, in doing so, an idea struck me, that the result of his demonstrations, when completed, may enable photographers who cannot afford large and expensive lenses to see a way of altering their small ones, by the *substitution of a longer focus back lens*, to get larger pictures when they may want them. Lengthening the focus of their combinations, and, consequently, enlarging the size of their pictures without enlarging the aperture of their lens, would, of course, make it slower; but would the practical effect be to injuriously affect the quality of the photographic impression on the sensitised plate? and, if so, in what way? Perhaps you, or some of your readers, will be kind enough to answer this query in the Journal, and thus oblige, VERDANT GREEN, AND MANY MORE.

Aberdeen, 21st February, 1860.

[The plan suggested is not practically available, because the cost would be nearly as great as for making a new entire lens, while the result would be very inferior.

There are, however, two methods already in use that meet the desideratum to some extent:—first, the substitution of an achromatic *concave* for the back lens of the combination, thus converting it into an "orthoscopic;" and, second, the introduction of a smaller achromatised concave *between* the existing lenses, as first practised by Mr. Archer, and at present in common use in Derogy's lenses. This latter arrangement is the one which we think will meet the requirements mentioned in your private note.—Ed.]

SATURDAY HALF-HOLIDAY.

To the Editor.

Sir,—When an Englishman has a grievance he writes to *The Times:* when photographers are in difficulties they write to The British Journal of Photography, and the courteous editor answers all their inquiries, and sets them right.

Now, sir, I, in common with many photographic operators, have a grievance. It is this:—my health is in danger, from constant confinement in the operating room, in an atmosphere almost saturated with ether, and loaded with the gases common to such places, and this, too, all the year round, nine or ten hours a day, without change of scene or the slightest variation in the routine. Do you wonder, sir, that, under such circumstances, photographs are not always artistic?

My object in writing to you is this:—to obtain your advocacy for the Saturday or weekly half-holiday for the operators of the city. The advantages both to employer and employed are so obvious as to need no argument; and I think a few words from you would accomplish a work for which you would deserve and receive the everlasting gratitude of all connected with our art. I inclose my name for your private satisfaction, and beg to subscribe myself AN OVER-WORKED OPERATOR.

London, February 10, 1860.

[We quite concur in the advisability of the movement here advocated. We know well the depressing effect arising from constantly inhaling the fumes of ether, to say nothing of the prussic acid from the cyanide of potassium.

We have no doubt that a weekly half-holiday would be a real advantage in the long run to both employers and employed. The particular day selected is of no consequence: let that day be chosen that is generally found to be least occupied. We verily believe that all would be gainers by the arrangement.—Ed.]

PRESERVATIVE CASES FOR POSITIVE PAPER.

To the Editor.

Sir,—I inclose a scrap of paper, which was printed on Saturday last, the 11th inst., and which was sensitised on the 12th October last. It is part of a lot put in one of my preservative cases at the last mentioned date. The print contains no pure whites, but the colour of the back affords good evidence of keeping.—I am, yours, &c.,

Glasgow, 13th February, 1860. WM. CHURCH, Jun.

[The print sent is as perfect as if the albumenised paper had been used within a few hours from the time of sensitising, instead of being kept for nearly *four months*. There is not a vestige of discolouration.—Ed.]

WAXED-PAPER PROCESS.

To the Editor.

Sir,—Having some idea of commencing the waxed-paper process, which is, I think, the most convenient one for a traveller, would you be kind enough to inform me, in your next issue, what is the best work on that process, and likewise whether it is one in which I am likely to succeed?—I am, yours, &c., S. M.

Liverpool, Feb. 20, 1860.

[We have read with much pleasure a little pamphlet on the waxed-paper process, translated from the French, by Mr. How, and published by Knight & Co., of Foster Lane. The formulæ there given will undoubtedly produce pictures of a superior quality, and we think you could not do better than give it a careful trial.—Ed.]

ANSWERS TO CORRESPONDENTS.

Amateur (Leeds).—A single combination.

C. B.—Consult our replies in No. 110.

A——m.—Aqua regia is a mixture of hydrochloride and nitric acids.

S. M. S.—India rubber solution is a capital vehicle for mounting your proofs.

Beatus.—"Contentment is better than riches." Need we say more?

Simplex.—You have spoiled your toning bath. Let well alone in future.

M. A.—It is probable that you used *hard* water. Take boiled rain, if you cannot procure distilled, water next time.

Newton.—Save all your washings containing nitrate of silver of course, and convert the solution into chloride by the addition of a solution of common salt.

Timon.—Why not apply to the secretary? He will most probably be able to find some one who knows you personally.

T. A. P.—Murray & Heath, Piccadilly, London, have lately introduced a very handy portable sink for a tent or developing box.

Sam.—Apply for a price list, enclosing a penny stamp, and you will get the information sought.

Mary J——.—You can procure gloves of india rubber, and then you need not fear to stain your fingers. See reply to "Enquirer."

Enquirer.—We have ascertained that the gauntlets about which you enquired are to be had at No. 58, Charing Cross, London.

T. M. (Manchester).—A four-inch landscape lens would be too large. One of two and a quarter or two and a half inches diameter would be ample.

Brisbane.—We have great hopes of the process recently introduced by M. Poitevin. We hope to have more to communicate thereon in a future number.

S. N. M. (Bembridge).—We are not quite certain that we have interpreted your initials correctly. Apply to Frith & Hayward, Reigate, and we have *no* doubt that your want will be supplied.

George Haydon.—We have never before heard of such an instrument as you describe: had we done so and noticed it, we should have done so simply to point out its absurdity. It is *impossible* to obtain stereoscopic effects from *single* pictures.

T. R.—We think if you were to work upon paper prepared as indicated in some of Dr. Maddox's recent communications, you would accomplish your object. Send a stamped directed envelope, and we will enclose you a specimen received from that gentleman.

Bosh! (Reigate).—Your signature is a little obscure, but looks like what we have given. Your proposed communication would scarcely be appropriate to *our* columns. Try the contemporary you quote.

S— W—.—You ought to have known better than to fall into such a palpable trap. Valuable recipes are not given for a few postage stamps. The amount laid out in a good manual would have supplied you with a dozen far better than that you have received.

Amateur (London).—The sum you have named is not much more than half what would be requisite to procure *the best*, but you will get very good of any of the makers you have mentioned. Perhaps the *third* on your list will answer your purpose best; we have frequently purchased articles of that dealer, and found them good.

Stereographs.—We have several sets of these productions to notice, and beg the kind indulgence of the artists for our delay, which has arisen partly from want of space, but chiefly from a serious attack of illness, which precluded the possibility of working at so laborious an occupation.

Rev. T. K.—We fear that some of the back numbers to which you allude are now out of print. The toning processes mentioned are to be found at pages 4, 74, 175, and 282 of our last volume. We cannot, however, meet your views better than by referring you to an excellent paper by Mr. Hughes on the subject about which you inquire, which paper appears in the present number.

Received.—J. Jones, W. R., B. F.

*** Again a plethora of matter compels us to leave over numerous interesting articles in type, among which are a Notice of the Architectural Photographic Association's Exhibition, and "Notes of a Photographic Tour in the Holy Land. No. XIV."

☞ *All* Editorial *Communications*, Books for Review, *&c., should be forwarded to the Editor*, GEORGE SHADBOLT, 2, *Upper Hornsey Rise, London, N.*

All Advertisements *and* Letters *on the* Business *of this* Journal *should be addressed to the* Publisher, 32, *Castle Street, Liverpool.*

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 114, Vol. VII.—MARCH 15, 1860.

In a recent report of a meeting of the Birmingham Photographic Society, it is recorded that Mr. Osborn mentioned the singular fact that a dry sensitised-collodionised plate, prepared by Dr. Hill Norris's process, after having been exposed to light, could be restored to a sensitive condition by being submitted to the action of the vapour of acetic acid. We do not perceive the *rationale* of the phenomenon; but that the fact is as stated we have no doubt, seeing that we have also the corroborative evidence of Mr. Hardwich, who at our request kindly tested the point. We should be glad, however, to learn from Mr. Osborn whether he has found the operation practically useful, as Mr. Hardwich is scarcely impressed with the idea of its being so, having found a plate thus treated to require a long exposure for the second latent impression, and also to develope with an immense number of minute transparent spots, which were not found on plates prepared at the same time, and with the same collodion, but not acted upon by the acetic acid. It is a matter that, in our opinion, certainly deserves further investigation: there are few well-established phenomena which cannot be turned to some account.

We find that the time has arrived when it has become requisite for us to make a few comments upon a lens that has been for some months before the public, and upon which we have hitherto maintained a strict silence. The objective to which we allude is that named by its inventor, Mr. Sutton, of Jersey, the *Panoramic Lens;* and our abstinence from any earlier notice of it will be readily understood by those of our readers who have observed the insults to which we have been subjected by that individual in his capacity as editor of a contemporary publication—insults so gross that we have not deemed them worthy of remark, and to which we should not even now have made any allusion but as accounting for our apparent neglect of a matter that might be considered as of interest to photographers generally. All those who are acquainted with us personally, and many more who know us only by reputation, will be aware that the above-named considerations are not likely to influence us in the smallest degree in rendering what we believe to be strict justice in any observations that we find it necessary to make. Without further preface, therefore, we proceed to lay before our readers such particulars as we have gathered, and to express, in reply to several inquiries that we have received, such opinions as we entertain with regard to the lens in question.

The panoramic lens, which we have inspected at the establishment of the authorised manufacturer, Mr. Cox, of Skinner Street, Snowhill, and more recently at a meeting of the Photographic Society, consists of a sphere of glass made in two hemispheres, with a water-tight fitting, and having a centrical spherical hollow space which, when the lens is in use, is filled with distilled water—thus forming a sphere of water within the sphere of glass, both having a common centre, the diameters of the two spheres being approximately as about one to two—that is to say, the glass being two inches in diameter has a central aperture of about one inch. The whole of the central opening is not, however, employed as the aperture of the lens: the water-tight fitting, before mentioned, projecting into the water, is made to act as a diaphragm, which reduces the aperture to a little more than three-eighths of an inch; and in addition to this an arrangement is introduced, which is termed by the inventor an *equalising stop*, and which consists of three or five plates radiating towards the centre of the combination, but leaving the centre unimpeded, the object of which is to equalise the amount of light transmitted by the lens, whether the rays pass through it perpendicularly or obliquely to the diaphragm.

It will of course be perceived that, by the arrangement above described, the axis of all pencils of rays, whether oblique or not, pass through the centre of the combination, and that the foci of very distant objects are situated on a spherical surface, having the centre of the lens also for its centre.

The angular extent of field intended to be covered is 120 degrees; but, inasmuch as such an extent would be totally useless in one of the two directions — that is, vertically—and that a surface of such extent of a spherical form would be inapplicable for any useful purpose, the inventor of the lens has substituted for a segment of a narrow spherical zone one of a cylindrical form, trusting that the more general proximity of objects in the foreground of a subject to be delineated will (by their posterior conjugate foci being thus necessarily farther removed from the lens than those of the distant objects falling centrically) compensate for the departure from the strict theoretical form of surface upon which the sensitive film should be found. It consequently follows that the plates upon which negatives are taken by the panoramic lens must be bent into the form of *one-third part* of a cylindrical zone, the dimensions being 6 × 15 in., or in about that proportion.

We believe that the preceding description includes all the peculiarities of the lens: the camera and other apparatus are of course modified to suit the requirements of the lens, that is to say, with backs to receive curved plates, and with baths and cleaning boards, printing-frames, &c., of a like character.

So far as we are aware the lens thus constructed is novel: it is certainly ingenious—the equalising stop especially so, and unquestionably does credit to the inventive faculties of its projector. It is therefore by no means surprising that he should expect great things from it—that he should regard it with a sanguine eye—be "to its faults a little blind"—and vaunt its qualifications in language not a little hyperbolical. All this is very natural, and we will therefore refrain altogether from criticising too closely the assertions made in the enthusiasm of the moment.

We fear, however, that instead of the panoramic lens being destined to supersede every other lens at present in use, as its projector so fondly imagines, on the contrary, its employment will be of a very limited character, and we shall of course adduce our reasons for arriving at this conclusion. We may first, however, remark, that we have seen the specimen print forwarded by Mr. Sutton to Dr. Diamond, and also very narrowly scrutinised the negative itself, which latter, he says,

is *as good as he can produce with the panoramic lens.* We are quite ready to admit that the print alluded to *does not do justice to the negative*, and that a much better one might be obtained from it. Having said this much, we now proceed to remark upon the negative. This we find but moderately sharp even for distant objects, and that only in about the central *third part of the negative*, which does not therefore exceed an angle of 40 degrees, the two lateral third parts being not in good focus, while the bulk of the foreground is very indistinct and quite out of focus. A very little consideration would of course lead us to expect that this should be the case; for not only does the correction for spherical aberration appear to be limited to reducing greatly the effective aperture, but *there is no provision whatever for focussing:* only those objects that are beyond a certain distance in front of the lens can be in tolerably correct focus for the central zone, while every other part must be delineated just as chance directs. It is contended by the patentee, that a portion of any subject, with ordinary lenses, must be out of focus more or less. This is true; but when a plane is the surface of delineation, the operator *has the choice* as to what part he shall focus upon specially,—and a most important point it is upon which to exercise the judgment.

The next feature to which we turn our attention is the asserted absolute freedom from distortion claimed for the performance of this lens. On this point we refer to another article in the present number, on "Perspective and Distortion;" and we will merely remark, that had only a tolerable "panoramic effect" been claimed, we should not have thought it necessary to point out the defect that undoubtedly exists as regards distortion.

The plates of glass employed with each lens must be bent to one particular curve, and this requirement, apart from any difficulties of manipulation—which by the way Mr. Sutton says do not exist—is such a formidable obstacle to the general adoption of the panoramic lens, that few persons would be likely to encounter it. Not only would the cost of glass be enormously increased, but the difficulty of obtaining a supply, under most circumstances, would deter many from adopting the curved plates.

The difficulties of coating curved plates, &c., are not only made light of, but absolutely ignored. We think that here Mr. Sutton will perceive his error on reflection; for he cannot seriously mean to assert that it is not more difficult to coat a cylindrical surface properly than a plane one. To ignore difficulties is not a promising way of conquering them; and it is not enough to say "that it can readily be done by using alcoholic collodion." Whatever may be the relative merits of ordinary and alcoholic collodion, it is not an easy thing to make any experienced photographer abandon the collodion with which he has been used to work.

We are convinced that there is increased difficulty in all the operations of cleaning the plates, coating them with collodion, developing and printing from them — reasons quite sufficient, particularly when taken with others previously mentioned, to prevent the bulk of photographers from casting aside their existing lenses in favour of this new one. Could it be shown that the real advantages were such as are so ostentatiously claimed, some photographers doubtless would take the trouble to conquer the manipulative difficulties; but, even then, we are of opinion that they would form but a small minority. In conclusion, we have again to remark that, while we fully appreciate the ingenuity of the contrivance, we consider that it is not destined to effect the revolution contemplated by its contriver.

It is with much pleasure that we feel called upon to announce the successful formation of a new Photographic Society in Scotland, a report of the first ordinary meeting of which will be found in the usual division of our present number, under the name adopted by the promoters—"The City of Glasgow and West of Scotland Photographic Society."

We are able sincerely to congratulate the members upon their very judicious selection of a President in the person of Mr. Kibble, a gentleman who possesses theoretical as well as practical acquaintance with the details of our art in no common degree; and we have much satisfaction in recognising several of the names amongst those of the office-bearers and council. The new society has our best wishes for a prosperous and useful career.

PERSPECTIVE AND DISTORTION.

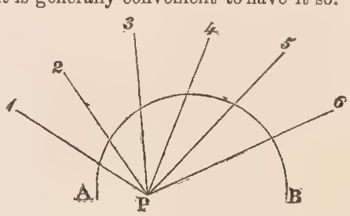
By Thomas Grubb, M.R.I.A.

It occurs to me that a short chapter on perspective may not be without its use at the present moment. I do not say that a long one would not be useful: there are some points in perspective which ought to be better understood. For the present, having a definite point in view, I shall, in progressing towards the same, avoid, so far as practicable, all complicated questions.

A picture (by which general term I propose to indicate an outline drawing, a finished painting, a photograph, &c.) can, strictly speaking, give a correct perspective view of a subject only from one point of sight; and for ordinary cases the plane or flat surface is at once the most convenient and desirable for adoption, having, together with other advantages, this important one, viz., that it is the one which produces a minimum amount of distortion for a given amount of displacement of the eye from the point of sight. In other words, pictures in general (I exclude, for example, such as necessarily embrace a circle round the spectator) suffer less distortion by the displacement of the eye from the true point of sight if projected upon a plane surface rather than upon any other which can be devised. Hence the general adoption of the plane whenever such is practicable.

Calling the preceding my first proposition, my second is capable of much easier proof, while it in no respect depends upon the first for its correctness. It is as follows:—

That a correct perspective picture can be produced for a given point of sight upon a surface of any form, provided such surface do not *return within itself* (or overlap) to the eye at the point of sight. Thus, the surface of representation may be flat, spherical, cylindrical, or irregular. Moreover, it is not required that the point of sight shall be symmetrical with the surface of delineation, though it is generally convenient to have it so. This is shown in Fig. 1,



where the curved line A B represents indifferently a section of a cylindric or spherical surface of delineation (which we shall suppose to be transparent and non-refracting); P the point of sight which is here placed neither in the axis of, or in any way symmetric with A B.; 1 P, 2 P, &c., rays proceeding from the several points of a distant object through the transparent medium A B to the point P. Now, if we suppose that the several rays 1 P, 2 P, &c., in passing through the medium A B, leave each their impression thereon, then an eye placed at P would find the images (so impressed) to coincide in direction with the respective parts of the object, and, *ergo*, to form a true perspective delineation of the same; for that which forms an outline on the retina of the eye perfectly similar to that of the original object must give a true perspective thereof, and this is effected under the circumstances described, *irrespective of the shape* of the medium or surface A B.

My next proposition is simply the converse of the preceding, viz., that having obtained a correct perspective delineation on a curved surface (whether by drawing, photography, &c.,) for any assumed position or distance of P (the point of sight), the same will *not* give a correct perspective to an eye placed at any other point, while the greater (*i.e.* the deeper) the curvature of the surface of delineation, the greater will the distortion be for any given amount of displacement of the eye from the true point of sight. It is probably unnecessary to stop to prove the correctness of this.

We have now arrived pretty close to the point which it is the more immediate object of this communication to treat on. I may of course be in error as to the opinion generally held with regard to this point; but it would appear from what has been lately put forward, as also from individual opinion privately expressed, that a very general error prevails with respect to it. In short, it would seem that a general impression exists that if we

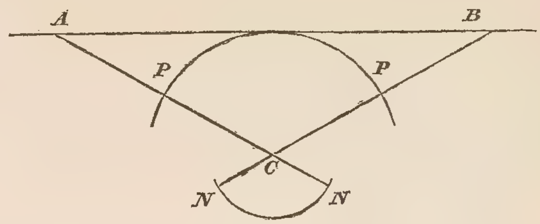
project or delineate, graphically or photographically, upon the surface of a cylindric segment a subject, in such manner that to an eye placed at some point in the axis of the cylinder the picture affords to the eye a true perspective of the original, we may either by unfolding (flattening out) the cylindric segment, or by copying from the cylindric picture and flattening out the copy, produce a picture which, in this its flattened state, will give a true perspective of the original to an eye placed at some definite point in front of the same.

Let it not be supposed that I am going to be over-precise or over-nice here. Where the *angle of view* is small, say 30 or, perhaps, 40 degrees — that is to say, 15 to 20 degrees on each side of the axis (or centre of the picture) — we may convert the surface on which a picture is depicted from a cylindric or spherical surface of *moderate* curvature to a plane, or reverse these operations, without incurring any serious amount of distortion; but a proposal having lately been made, as I understand, to take pictures (photographs) on a cylindric segment of 120 degrees, and to obtain from these, by photographic means, pictures upon a plane free from distortion, it becomes a matter of some interest to investigate the practicability of the proposal.

In our present state of knowledge there appear to be just two ways in which the most sanguine imagination can hope to accomplish this:— one by the aid of a lens; the other by the process of ordinary photographic printing.

Commencing with the consideration of the former, I shall suppose that, having procured a panoramic lens of, say eight inches focus, with the required curved glasses, &c., we obtain a curved negative, including an *angle of view* of 120 degrees; and that we next proceed to copy this negative by the aid of (of course) a panoramic lens, in the proportion of two to one, *on a flat surface.* The first thing which must here strike us is, that our eight-inch lens will not effect this; in fact a copying lens is required for each proportion of original and copy. In the case assumed, the focus (principal) of the copying lens must be five and one-third inches, which will give conjugate foci of eight and sixteen inches, as required. This second lens being procured and placed in the axis of the cylindric negative, would afford a picture or image of the same in the required proportion of two to one, but, unfortunately for the scheme, *only on a curved surface of the proportionate radius* (here of sixteen inches). This is

FIG. 2.



shown in Fig. 2, where C is the centre of the lens, NN section of the curved negative, PP section of the segment on which the lens would form an image of N N; while to form a distinct image on the plane indicated by the line A B, the lens should be at once five and one-third inches focus for the central rays, and six and four-tenth inches focus for the extreme lateral ones. I need hardly say that to suppose such a lens as possible of construction is too absurd to be entertained for a moment; while if we attempt to *accommodate matters* by placing the copying lens *out of* the centre of curvature of the curved negative, we get a bravely-distorted picture.

To sum up the resources of copying by the lens —

1. We may obtain a picture on a flat surface free from distortion, but unbearably indistinct.
2. We may obtain a picture (also) on a flat surface tolerably* distinct, but greatly distorted.
3. We may produce (but only on surfaces the curvature of which is in strict accordance with the circumstances) pictures similar in size, outline, and projection, to what would be obtained on similarly curved surfaces by using, in the first instance, a lens of the required focus.

And of these three resources I shall here observe that while the first and second appear to be of no practical use, the third places us no nearer than we were without it to the obtaining of a true perspective picture on a flat surface.

Turning now to the consideration of the second proposed method, viz., that of copying from the cylindric negative by the ordinary photographic printing process, the investigation of which is the chief end of this communication, I shall best explain my view of the inevitable result by the aid of a triple diagram.

FIG. 3.

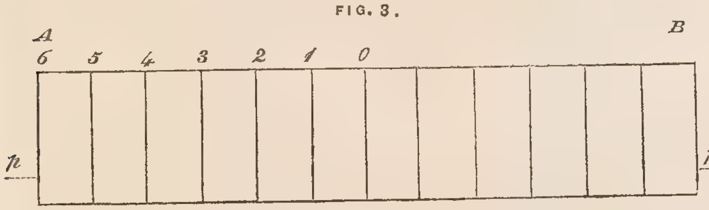


Fig. 3 represents an undistorted front view of a long range of building, divided, vertically, into equal spaces, by lines numbered from the centre (*o*) towards either end, *p p* representing the height of the line of sight.

FIG. 4.

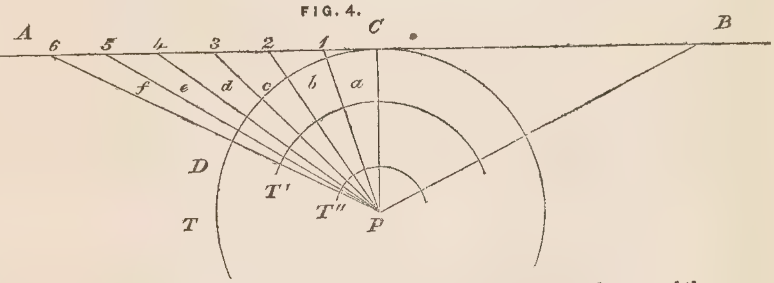

Fig. 4 is a ground plan or section of the same through the horizontal plane of sight (fig. 3, *p p*).

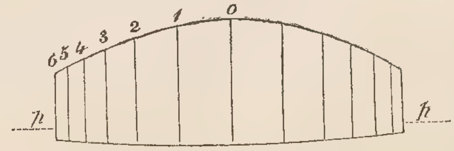
The line A C B corresponds in length with Fig. 3, and is similarly divided and numbered. P is the point of sight, placed centrally opposite to A B, and to which A B subtends 60 degrees on either side of the perpendicular P C.

Let the line A C B be also considered as representing the position of a transparent vertical plane, through which the building (Fig. 3) is seen from the point P, and let T T′ T″ represent the position of several transparent cylindric surfaces, placed vertically, and with their axes coinciding, with the point P.

Then will the several diagonal lines or secants *a b c*, &c., in their contacts with the transparent plane A C B, and with the several concentric segments T T′ T″, show the respective places where corresponding points will be found for each of these surfaces. It is perhaps unnecessary to mention that the several cylindric segments being placed concentric, the projection on any one will be the same, except in size, with the rest. Selecting then that segment which touches the transparent plane at C, we find from the diagram that, while equal horizontal spaces (in the object) are indicated on the plane A B by equal spaces, the same are, on the segment C D, indicated by spaces widely differing. In short, we substitute, in using the cylindric projection, the *arcs* of the several triangles C P 1, C P 2, &c., for their tangents C 1, C 2, &c.

FIG. 5.



* Only a narrow horizontal band can, under any circumstances, be expected to be distinct.

These arcs are represented in due proportion by the vertical lines 0 to 6, Fig. 5. To complete the projection we must now find the lengths for these several lines, above and below the line of sight.

Vertical lines (in the object) being represented in both the plane and cylindric projections by vertical lines, we have a law common to both cases for ascertaining their length, viz.:—

Multiply the height of the object by the fraction which represents the proportion which the distance of the surface of representation from the centre P bears to the distance of the object from the same, or

$$h = H \times \frac{d}{D}$$

For example: suppose the height of the object to be 400 inches, the central distance — viz., from P to C, Fig. 5 — 800 inches, and from P to the transparent surface 8 inches, then

$$h = 400 \times \frac{8}{800}$$
$$= 4 \text{ inches}$$

Taking for another example the extreme point of the object (subtending 60 degrees to the vertical P C), we find its distance to be *double* that of P C; so that

$$h = 400 \times \frac{8}{1600}$$
$$= 2 \text{ inches}$$

and by calculating the lengths of the remaining five lines of our diagram, we obtain the projection shown at Fig. 4.

It will be seen that I have treated this part of the subject independent of the presence of a lens; but it may also be seen that, provided the lens (as stated of the panoramic) converges the rays without deflecting the pencils, then it is perfectly immaterial to the accuracy of our deductions whether the investigation is conducted by considering the several axial rays as they pass through a surface before arriving at the centre P, or as they pass through the same surface similarly placed behind P, and after having passed through the same.

In order that the photographer may understand what he may expect in the way of perfection or distortion by adopting a certain course, I recommend a comparison of Figs. 3 and 4. Let him suppose that, desiring to take an undistorted view of a building or range of buildings, the length and height, &c., of which are in proportion to the diagram Fig. 3, he takes a negative (the object subtending an angle of 120 degrees) on a cylindric surface, and then having printed a positive from the same by superposition, he unfolds or flattens out the positive. Now, Fig. 3 being assumed to be an undistorted view of the object, Fig. 4 is the *panoramic*.

Since writing the foregoing, a case has occured to me which affords a striking illustration of the effect of changing the figure of a surface of representation, on which a perspective delineation had previously been impressed.

A picture of the interior of a *circular building* being projected upon a cylindric surface from a point of sight in its axis—the centres of curvature and point of sight being all symmetric — this picture, on being unfolded or flattened into a plane, will be a true perspective front, or direct view of a *perfectly straight line range of building;* and (conversely) if we project upon a plane a true perspective front view of a long *straight* range of building, and bend it into a cylindric segment, it will, to an eye placed in the centre of curvature, and in the original plane of sight, present the effect and true perspective of a *cylindric* interior. This rather striking metamorphosis, which I am not aware of having been previously noticed, may prove, on occasion, of essential help to the artist; but I mention it here chiefly as being one of the many proofs which can be adduced of the absurdity of assuming that what is true perspective on a cylinder viewed from a definite point, is when unfolded, a true perspective of the same subject viewed on a plane.

ON THE MANUFACTURE OF PHOTOGRAPHIC COLLODION.

By T. F. Hardwich.

[Read at the Meeting of the London Photographic Society, 6th March, 1860.]

The manufacture of photographic collodion could not be described in a paper of the ordinary length, without omitting many important points, and treating others in a superficial manner. I am, therefore, compelled to make a demand upon your patience, but will do all that lies in my power to assist the comprehension of the subject, by dividing it into separate portions. To commence, then, with the chemicals which are used in the manufacture of collodion.

1. *The Cotton.*—For sometime after I began this process, I purchased cotton of Messrs. Hutton & Co., of No. 6, Newgate Street, City, without knowing anything of its manufacture, excepting that it was the finest quality procurable, and cost two shillings per pound. Afterwards, however, I thought it better to procure a variety of samples of cotton wool of different growths, which I was enabled to do by the assistance of a friend, who sent some fourteen or fifteen packets, grown in America, Madras, South Sea Islands, &c., and ranging in price from fourpence halfpenny to fourteen pence per pound. Having prepared the nitrosulphuric acid in the manner presently to be indicated, and found by trying it with the ordinary cotton that it was of the correct strength, I divided it out into equal measures, and immersed about nine or ten of the most characteristic of the cottons. The result was a failure in every case, the material being in a great measure dissolved by the acid. None of these cottons had undergone any cleansing, and therefore, although many of them appeared sufficiently white and pure, it appeared desirable to try the effect of boiling in a weak alkaline ley. The process proved more successful than I anticipated, and enabled me to prepare pyroxyline from a sample of cotton which was otherwise immediately disintegrated and reduced to pulp by the action of the acid. Evidently the cotton fibre is encased by a film of some resin, which the alkali converts into a soap, and removes in a soluble form. Supposing this resin to be left upon the cotton, it resists for a little time the action of the nitrosulphuric acid, and much squeezing with the glass rods is required to wet the cotton and make it imbibe the fluid: bubbles of air are entangled at first, and cannot easily be expelled, but almost immediately afterwards an evolution of red fumes takes place, and the fibre is destroyed by oxidation. On the other hand, with the cotton which has been previously treated with dilute potash, there is no difficulty whatever in making it absorb the acid; it sucks up the liquid like a sponge, and remains nearly unaltered in appearance during the whole time of the digestion.

I cannot say that I have invariably pursued the plan of cleansing the commercial cotton wool by boiling in a weak alkali, since I was not at first aware of the importance of so doing. When, however, I observed the effect of the potash upon the raw material, I at once applied it to the commercial cotton, and with manifest advantage, for I now obtain at least fifteen per cent. more in weight of pyroxyline, and secure greater uniformity in every other respect. Even from the finest qualities of the wool, traces of soluble matter are extracted by potash, sufficient to impart a strong yellow colour to the alkaline liquid, and which, if permitted to remain, would deoxidise that portion of the nitric acid immediately in contact with the fibre, and so far weaken it as to insure the immediate solution of a part of the cotton.

It is always desirable to simplify a chemical process, when it can be done with impunity; but at present I am disposed to recommend this alkaline treatment of the cotton, since in purchasing the finest qualities previously, in quantities of twelve pounds at a time, I did not find them to correspond, which I now think may have been due to the greater or less perfection of the cleansing process; and without doubt the percentage gain in weight on converting the cotton into pyroxyline, has been greater and more uniform since the preliminary treatment with a dilute alkali was adopted.

The cotton which I use is of American growth, but not always from the same State, since it appears that the manufacturer is guided, in making his purchases, by the varying price of the market. This cotton is sent out in packets of one pound each, which I divide into quarters, and boil each quarter gently for two hours, in a solution of two ounces of potash (at 2s. 6d. per pound) to a gallon of water. The mass is then lifted out, and well squeezed in repeated changes of water for about twenty minutes, after which it is spread out to dry. The assistant to whom this preliminary part of the process is intrusted receives full directions to remove the whole of the potash, and to disturb the fibre of the cotton as little as possible, since if it become knotted and twisted the action of the nitric acid will be interfered with.

It may, perhaps, be suggested that the potash is likely to exercise a chemical or modifying action on the fibre of the cotton; but I do not think that it has any such effect when used in dilute solution, and for a comparatively short time, as I advise. I formerly believed that a prolonged digestion in a somewhat stronger potash might by degrees affect the cellulose, and produce more or less of that condition which we see in old and rotten calico, as compared with the new material; but there need be no apprehension of this in the process above described, because cotton fabrics which have been weakened by wear and repeated washings become more easily soluble in nitrosulphuric acid; whereas the cotton wool, by boiling in weak alkali, is rendered less soluble in the acids. I think it right, however, to mention that the use of the potash is a recent improvement, none of the collodion tested by the committee having been prepared from cotton so treated.

2. *The Sulphuric Acid.*—I have not derived any advantage from using the pure sulphuric acid, but have found the commercial acid sufficiently good for the purpose. The strength is a little variable, and therefore it is better to take the specific gravity of several samples, and to select the strongest. Sulphate of lead and bisulphate of potash are mentioned as impurities of commercial oil of vitriol; but I never detect the latter in any samples which are sent to me, and very seldom the former; from which I infer that the great and increasing demand for oil of vitriol in the arts has led to a gradual improvement in its manufacture. Traces of nitric acid are usually present in the commercial acid, but not to an extent likely to interfere with the preparation of pyroxyline.

3. *The Nitric Acid.*—I have been asked why I recommend so strong a nitric acid as that of sp. gr. 1·45, seeing that the acid is afterwards to be so greatly diluted with water. There are two reasons for so doing: first, because this acid is cheaper after the rate, and perhaps more uniform than a weaker acid; and, secondly, it is important that both the sulphuric and nitric acid should be as strong as possible, in order to allow of the use of sufficient water to raise the temperature on mixing at once to the proper point, and so to obviate the necessity of employing artificial heat.

A saving of expense is effected by using the yellow acid, sold in commerce as "acid nitros," in place of the pure acid of equal strength; and for some time I was of opinion that this might be done with impunity: it subsequently appeared, however, that the quantity of chlorine in the "nitros acid" is more valuable than I imagined; and on inquiry I find that it must necessarily remain so, inasmuch as the cargoes of nitrate of soda, from which the acid is made, differ in quality, and no preliminary process of purification is resorted to, with the view of eliminating the chloride. The effect of chlorine, when present in the nitric acid in more than a certain proportion, is to decompose the pyroxyline, and cause its partial solution in the nitrosulpuric acid. Hence it becomes necessary to work with a smaller quantity of water, and consequently an inferior pyroxyline is obtained, as I shall presently show. The chlorine also slightly modifies the composition of the pyroxyline in some unexplained manner, causing it to give more intensity in the photographic process, and lessening its keeping properties in collodion both before and after iodising. The pure acid answers perfectly, but I do not usually employ it alone, from motives of economy. The plan which I have followed has been to apply to the manufacturer, and ask him to pick out for me a carboy of the purest "acid nitros" in stock; this I test with nitrate of silver, and compare it with a standard kept for the purpose: if the chlorine exceeds a certain quantity, two carboys, one of pure nitric acid, and the other of acid nitros, are mixed in equal bulks. To give a notion of what the standard is, I may mention that if one drachm of nitrate of silver, dissolved in half an ounce of water, will throw down the whole of the chloride contained in half a gallon of the acid, the sample is sufficiently pure.

Besides chlorine, the "acid nitros" contains peroxide of nitrogen, imparting to it a yellow colour; but this, I think, enters into a fresh combination on the addition of the oil of vitriol, and produces no effect upon the immersed cotton.

4. *The Ether.*—Next to the pyroxyline, the ether is the chemical of most importance in making collodion, and I have always in this process felt myself to be at the mercy of the ether manufacturer. Indeed, the purity of ether is of more consequence with pyroxyline of the kind which I recommend than with some other varieties of that substance; and I think that the success of the present attempt to give a definite formula for collodion will depend very much upon whether the makers of ether can supply a uniform article in the desired quantity. What we need is an ether which, when mixed with an equal bulk of strong alcohol containing iodide of potassium in the proportion of three-and-a-half grains to each ounce of the mixture, will remain colourless for several days in the cold season of the year. Commercial ether usually strikes a yellow colour in less than half an hour when treated as above described, but in that case it cannot be termed pure. It is quite possible to prepare ether which will stand the test just mentioned, by proceeding in the following manner:—Take the best washed ether of commerce, and agitate it thoroughly with a small portion of dilute sulphuric acid, then introduce it into a retort, and distil over one-third of the total bulk. It first occurred to me to employ the sulphuric acid, from having noticed that ether which liberates iodine from iodide of potassium, often possesses an alkaline reaction to redden litmus; and since the last distillation which ether undergoes in being purified is from a caustic alkali, I thought it possible that small portions of some volatile organic body of a basic kind, might be carried over with the ether. Whether this be so or not, I am assured, beyond a doubt, that the quality of the ether is materially improved by this final distillation from diluted sulphuric acid; and therefore the additional cost, which cannot exceed sixpence per pound, must not be considered.* The reaction of the pure ether is still alkaline to redden litmus, thus showing that the whole of the acid remains in the retort: specific gravity ·722 to ·725 at 60°. At present I am not able to assert that the ether which I obtain is invariably constant in properties; so that there is room for further improvement, although when we compare ether of the present day with that which was sold in commerce a few years ago, the advance is very evident.

In connexion with this subject of ether, I would add two or three more remarks. It is possible to make any ether stand the test of iodide of potassium most perfectly, by agitating it with a little dry carbonate of potash; but the resulting collodion is, in fact, injured rather than improved by such a process, since the carbonated alkali decomposes the gun-cotton. When, however, we obtain a sample of ether which has been distilled from sulphuric acid, and yet find it to remain colourless for a long time on adding iodide of potassium, we may be assured of its perfect freedom from the "ozonised" principle.†

* The idea is to collect the first portion of the distillate for photography, and to use the remainder for medical or other purposes.

† The condition of ether known as "ozonised" is the same as that to which the term "acid" is often applied; but in testing samples of ether I rarely or never find them acid to test-paper.

The difference between bad and good ether is seen most evidently after long keeping. Supposing light to be excluded, a pure sample of ether may be placed in a bottle, only half full, and at the expiration of two or three months it will scarcely become coloured on the first addition of iodide of potassium. Ether only partially purified will often stand the test of iodide of potassium when freshly distilled, but it will soon acquire the property of liberating iodine when it is stowed away for keeping. Supposing, for instance, that traces of *aldehyde* be present, which is not an improbable notion, this aldehyde would gradually absorb oxygen, and the ether would deteriorate. We must bear in mind that all varieties of pyroxyline have more or less tendency to ozonise ether by degrees, although some are more stable, and consequently superior to others in this respect. Hence, with the best quality of ether, the collodion will not stand the action of iodide of potassium so well as the solvents minus the pyroxyline; but when we have to deal with an inferior ether containing traces of some more oxidisable body, then the peroxide of nitrogen in the gun-cotton will soon act upon this substance, and the collodion will not bear very long keeping without acquiring the property of becoming immediately yellow on adding the iodiser. To show that this difficulty, although requiring further investigation, is likely to be eventually removed, I may mention that a large quantity of collodion which I sent to a friend in Australia was stated by him to remain quite colourless for a time on adding a potassium iodiser, and in consequence the sensitiveness was very great. I do not not consider that any trace of alkali was present in this case to account for the non-liberation of iodine; if so, the collodion would have been slower than usual, instead of being more rapid. The absence of the ozonised condition after so long a voyage depended, doubtless, upon purity of the ether and stability of the pyroxyline. And with an equally good ether the same result might again be obtained.

A few words on the subject of "methylated" ether. I am quite ready to allow that a great improvement has of late been effected in the manufacture of this substance, and that it would not always be easy, even to an experienced person, to distinguish it from the pure ether. Nevertheless, it is certain that the use of methylated ether ought not to be encouraged in photography; for, independently of an action upon the bath which some attribute to it, how can we expect the same uniformity of product when an inferior spirit of wine is usually taken for methylating, and when, in addition, it is not in the power of the manufacturer to exercise any control over the naphtha which the government directs to be added. We know that the purity of ether depends very much upon that of the alcohol from which it is produced, and those foul-smelling organic substances which are often found in ether are really derived from foreign bodies originally present in the spirit. Observe that I am now speaking of ether for the finest description of collodion, iodised with an iodide only. When bromides and iodides are employed conjointly in collodion, the sensitiveness is not so much affected by the state of the ether, and hence the above remarks would perhaps be less urgently called for. Even then, however, the advocates of methylated ether may well be reminded that in the case of collodion prepared with equal bulks of ether and alcohol, the substitution of the cheaper form of ether cannot make a difference of more than one penny per ounce wholesale price.

5. *The Alcohol.*—For a long time I used rectified spirits of wine for the preparation of collodion, and increased its strength as far as necessary by means of dry carbonate of potash; but having at length become dissatisfied with the smell of certain samples of this rectified spirit, I was induced to employ a strong alcohol obtained by one distillation. In rectifying spirit, a liquid known as "faints" is sometimes used, containing alcohol, either strong or weak, but contaminated with essential oils; and since it is most important in photography to avoid that particular class of organic bodies, the grain spirit obtained by one distillation in a Coffey's still is to be preferred. In taking the specific gravity of this spirit, which I have found to vary from ·817 to ·819 at 60° Fah., we see at once the advantage likely to accrue from its employment, since the fousel oil, which boils at a more elevated temperature, cannot rise so high in the still, and is separated. The smell of this spirit is very sweet; and although it is not quite so strong as is required, yet by converting a portion of it into alcohol of ·805, by means of dry chloride of calcium, and mixing this with the remainder, the correct specific gravity may easily be obtained.

The reaction to test-paper of the pure grain spirit should be quite neutral; but I find in some instances that a trace of acid is present, so that each half gallon of spirit requires about one drop of the standard solution of ammonia alluded to in the third division of this paper, under the head of "Preparation of Plain Collodion." I have never yet found in this or any other spirit the alkaline reaction which is exhibited by ether.

6. *The Iodising Compounds.* — A few words will here be sufficient. It has been stated, as an objection to the iodide of potassium, that it cannot often be obtained in a pure form; but so far from such being the case, I have found the yellow crystallised iodide of potassium — that from which the last traces of carbonate of potash have been removed by neutralising with hydriotic acid — to be purer than any other iodide which is sold. It contains usually a little sulphate, but this appears to be inert. Of iodide of cadmium I cannot speak so positively, some samples being only partially soluble in spirit.

Iodide of ammonium is now prepared of good quality by a process of double decomposition; but formerly hydrosulphate of ammonia was

employed in its manufacture, and the product was then inferior, from the presence of traces of a sulphur compound. In other samples of iodide of ammonium I have detected large quantities of carbonate of ammonia, introduced for the purpose of keeping the salt in a colourless condition, and also of sulphate of ammonia. It has been stated by a respectable authority, in the pages of the *Photographic Journal*, that iodide of ammonium must be used whilst fresh; this I think is a mistake, since I have kept it for more than three years in an ordinary bottle; and, with the exception of a little coloration, which does not affect its action in bromised collodion, it is as good as at first.

Apparatus, &c.

The following articles will be found useful in preparing collodion on a large scale:—

1. *Porcelain Pots for the Acid.*—These I purchase of Messrs. Simpson, Maule, and Nicholson, Kennington Road, Lambeth. They are about 7 inches high, four inches in width at the top, and are provided with covers and handles; also with a rim near the upper part, which serves as a support when heat is applied. The glaze is very good, and is unaffected by the acid. They hold an imperial pint and a half.

2. *Glass Spatulas.*—These are made of thick plate-glass, and may be obtained at Messrs. Brown's warehouse, Farringdon Street. Length 10 inches, breadth $1\frac{3}{8}$ inches, thickness $\frac{1}{4}$ inch. I find them to answer better than rods for immersing and removing the cotton.

3. *Hot-air Bath.*—This is a simple apparatus for warming the pots containing the acid mixture, when the temperature is inadvertently allowed to fall too low. It consists of an open vessel like a saucepan, made of strong sheet-iron fastened by rivets, standing on legs over a Bunsen's burner. In the part corresponding to the cover of the saucepan is a round hole, into which the porcelain pot drops, until it is caught and supported by the rim. The pot does not touch the bottom, but approaches very near to it, and hence all danger of cracking is avoided, whilst sufficient heat can be obtained in a few minutes.

4. *Thermometer.*—Select an instrument with a wide column of mercury, so as to be easily seen by gaslight, and with a large bulb, that it may be sufficiently sensitive. It is quite necessary to compare the thermometer with a standard instrument, since I find that the cheaper thermometers constantly vary, to the extent of several degrees. It is useful also to have a second thermometer hanging up, with which to compare the first, since the column of mercury sometimes separates, leaving a vacant space, and thus indicating too high a temperature.

5. *India-rubber Gauntlets.*—These are indispensable, as a protection to the hands in making large quantities of pyroxyline: they may be obtained of Messrs. Matthews and Son, Charing Cross.

6. *Trough for Washing.*—It consists of a strong deal framework, 3 feet long by 2 feet wide, lined inside with gutta percha. The water passes in through two tubes, one at the end and the other near the centre, each being pierced with fine holes, so as to deliver the water in a series of jets, and keep up a constant current at every part of the tray.

7. *Steam-bath for Drying Cotton, &c.*—This may be made by first constructing a flat zinc tray, 2 feet wide by 4 feet long, with a tightly soldered cover, and standing on short legs. The water is boiled in an ordinary tin saucepan, and the steam conducted by a pipe about 3 feet long, well rolled in list or flannel, into the closed tray, the condensed water being allowed to drop out at the end. Pyroxyline may be dried with safety upon this bath, since the flame is placed at a sufficient distance; and the heat can be regulated at will by adjusting the supply of gas. If the upper zinc plate be covered with flannel or calico, the temperature does not rise higher than 130° Fahrenheit.

Preparation of Collodion.

1. *The Pyroxyline.*—I have always adopted the plan of laying in a large stock of acids at one time, since it is somewhat troublesome to ascertain the exact strength, and no mode of analysis seems to be perfectly satisfactory. The manufacturer sends in three carboys of oil of vitriol, holding six gallons each, and one carboy of strong nitric acid of the same size. These are bottled off into Winchester quarts, or half-gallon stoppered bottles (labelled No. 1 for the first carboy, No. 2 for the second, and No. 3 for the third), for the sake of greater convenience in handling, and to lessen the chance of the acid absorbing water from the atmosphere. As the strength of the oil of vitriol in each carboy is different, a mixture must be made of No. 1, No. 2, and No. 3, taking a single bottle of each. Then, supposing the specific gravity of the acids to be nearly as before given, mix as follows:—

Oil of vitriol, 1·843 at 60° Fah.......	18 fluid ounces.
Nitric acid, 1·457 at 60° Fah.........	6 „ „
Water.............................	$5\frac{1}{4}$ „ „

Pour in first the water, then the nitric acid, and lastly the oil of vitriol; obtain a perfect admixture by stirring, and take the temperature. If the thermometer rises to 165° or 170° Fah., the acid must be allowed to cool until it stands exactly at 150° Fah. Then immerse the cotton in pieces well pulled out, and weighing thirty grains each, continuing to put them in singly until *ten* have been introduced, making 300 grains in all. This operation, together with the pressing against the sides of the vessel, &c. (to be alluded to again presently), will occupy about two minutes, after which the vessel may be covered up and left for eight minutes more. Then take out the whole of the pyroxyline in one lump with glass spatulas; squeeze out as much of the acids as possible in a porcelain capsule, and dash the whole into a large quantity of water.

An experienced person will be able to judge at this stage of the process whether he has hit the right point. If, on attempting to lift out the whole mass of pyroxyline at once with the glass spatulas, it seems rather small in quantity and very rotten, so that little pieces break away and are left behind in the acid, then the temperature is too high, or the acids are too weak, and in repeating the operation the quantity of water may be diminished by two or three drachms. If, on the other hand, the mass of pyroxyline appears large, sticks well together, and shows no tendency to tear, either the temperature has fallen several degrees, or it will be advantageous to work with a few drachms more of water.

Whilst the pyroxyline is washing in the tray, it is still more easy to judge of its quality; for if the ten separate pieces, in which the cotton was originally weighed, are seen floating about, and can be separated and counted, the acids are certainly too strong; whilst if there be an evident aspect of commencing solution—a piece of cotton here and there scarcely changed, but the others in a measure broken up, and tearing easily under the finger—the operation is probably successful; but when the whole is so mixed up together that nothing but fragments of the ten pieces can be detected, then the pyroxyline is too weak.

I find that it takes twenty-four hours to ensure the proper washing of the pyroxyline, even in a slowly running water which contains a portion of chalk. This carbonate of lime evidently acts in neutralising the acid, and bubbles of carbonic acid gas form, which bring the cotton by degrees to the surface of the water, and keep it floating.

After a thorough washing, the pyroxyline is squeezed in the hand, and then picked out to dry upon a cloth. A boy performs this part of the operation; and after a little experience, he can tell easily whether the material was properly made, partly by the extent of surface which it covers upon the cloth, but more easily by the readiness with which it tears under the fingers. If it resembles the original cotton in appearance, and feels strong and tough, the amount of water in the acids must be increased; but when it breaks up into little bits, as it should be, or else is somewhat too weak, in which case the fragments will mat together, so as to increase the difficulty of picking them out. As the pyroxyline dries upon the cloth it is well to examine it and give directions accordingly, separating any piece which appears less acted on than the rest.

Two or three days' exposure to the air will render the soluble cotton sufficiently dry; but it is convenient to finish it off on the hot steam-bath before described, and the temperature in which is not allowed to rise higher than 120° Fah. When dry, proceed to weigh it on the scales, and form your estimate of its value accordingly. A long experience convinces me that, supposing nothing to be lost in the washing, the weight of the resulting pyroxyline is a certain and safe guide in this process, and I can always tell what the quality of the collodion will be by using the scales. If 300 grains of cotton yield 450 grains of pyroxyline, it is certain that complaints will be made of the resulting collodion being thick, and giving streaky pictures: four or five additional drachms of water in the nitrosulphuric acid will be the remedy. When the weight of the pyroxyline is the same as that of the original cotton, viz., 300 grains, there will be a sediment on dissolving it in the mixed ether and alcohol; nevertheless the collodion, although lessened in quantity, will be good,—very limpid and structureless, with great adhesion to the glass, less tendency to markings of all kinds, and considerable softness of negative, with sensitiveness to dark rays. The chance of spots, however, is peculiarly great with this collodion; for if the smallest particle of dust touch the film, it will almost certainly arrest the development, and produce a transparent circular mark.

The weight which on the whole I think to be best is 375 grains, that is to say, exactly 25 per cent. of increase: this gives sufficient fluidity of collodion, and at the same time leaves very little sediment in dissolving.

The above facts are quite reliable, since they have been verified by repeated observation, extending over a long time. It must, however, be distinctly understood that the weight of the pyroxyline can be taken as a criterion of quality only under the conditions stated in this paper,—the fibre of the cotton must be cleaned by potash and quite dry, the nitric acid nearly free from chlorine, the time of immersion always the same, and, most important of all, the temperature correctly ascertained, otherwise the weight will be so variable that nothing can be deduced from it, and the cotton may be considerably acted on, even when the acids are strong enough to produce an explosive variety of pyroxyline. The whole process, in fact, requires care, because it is conducted with the maximum quantity of water, and at a high temperature. At least 20 per cent. of the pyroxyline is dissolved in any case; and the acids having once begun to act, will readily destroy the remaining portion of the fibre, if an error be permitted.

Before passing on to the preparation of the collodion, it may be mentioned that the quantity of pyroxyline which I find it convenient to make at one operation is four times that stated. A double quantity of acids (36 ounces of sulphuric and 12 of nitric) is mixed in a jug, and poured into the porcelain pots before mentioned. The first 300 grains of cotton are then immersed and left digesting, whilst the second similar portion is put into vessel No. 2. When the pyroxyline has been removed, the acids are emptied out, and a double quantity again mixed as before. At one time I adopted the plan of using the old acids again, by adding oil of vitriol to restore the strength, but afterwards discontinued it as causing uncertainty.

The Plain Collodion.—This is made by introducing half a gallon of alcohol of ·805 into a two-gallon stoppered bottle, and adding 1900 grains of dry pyroxyline. When the pyroxyline has become thoroughly saturated with the alcohol, pour in half a gallon of ether of ·725, and agitate for two or three minutes; next add another half gallon of ether, and again shake the bottle for a few minutes. After this the collodion may be allowed to settle for about a week or ten days, when it will be sufficiently clear for use. The quantity of pyroxyline may be increased to 2200 grains when a collodion of some body is required, or reduced to 1800 for a thin collodion suitable for large plates. Supposing the height of the column of collodion as it stands in the bottle to be ten inches, the sediment measured twenty four hours after mixing is often about half an inch, but it settles down more closely at the expiration of a week or ten days. If the sediment should stand as high as two inches in the bottle, the collodion is probably of that kind which has been described as giving a soft negative with a tendency to white spots. The above point being of importance in a commercial point of view, I have taken pains to collect the sediment from more than two hundred gallons of collodion, and find that the loss does not exceed one pint in fifty. It appears at first to be much greater than this; but the residue continues to settle for many months, the clear collodion being occasionally drawn off from the upper part and added to the general stock, a small portion at a time. I have sometimes thought that the proportion of *undissolved* matter is greater when the pyroxyline has been dried by artificial heat; but I am not able to speak positively, since I usually dry by spontaneous evaporation.

On the day following the preparation of the collodion, about half of a fluid ounce may be drawn off by a pipette from the upper clear portion, and a minute piece of red and blue test-paper immersed for twelve hours. If, at the expiration of that time, the blue paper appears reddened, the pyroxyline was imperfectly washed, and the standard alkaline solution, which I shall immediately describe, is dropped into the plain collodion in the proportion of one full-sized drop to each half-gallon. This addition of alkali is seldom required in my practice—certainly not oftener than once in twenty times. If, however, the pyroxyline be removed from the washing-tray at the expiration of twenty-four instead of forty-eight hours, traces of acid are generally to be detected in the collodion. To make the standard solutions which are required, dilute the nitric acid of 1·45 with an equal bulk of water for the acid, and then dilute down the strong ammonia of commerce also with distilled water, until a fluid drachm exactly neutralises a corresponding bulk of the standard acid. With these two liquids at hand no further trouble will be experienced, since the quantity of acid left in the pyroxyline varies very little; and if any number of drops of ammonia be added in excess, a corresponding number of the acid liquid will neutralise them.

The Iodising Solutions. — There are three iodising solutions, made by the following formula: —

No. 1. (Potassium iodiser): —

Alcohol, ·817 at 60°	$1\frac{1}{2}$ gallon.
Iodide of potassium	3200 grains.

It is necessary to pulverise the iodide very carefully, and to warm the spirit in a glazed covered saucepan to about 120° Fah.; after which, on drawing it off into a stoppered carboy, perfect solution will take place with ten minutes' shaking. Filter through pure bibulous paper.

No. 2, (Cadmium iodiser): —

Alcohol, ·817 at 60°	$1\frac{1}{2}$ gallon.
Iodide of cadmium	4000 grains.

Dissolve in the cold; no pulverising required.

No. 3. (Bromo-iodide): —

Alcohol, ·817 at 60°	$1\frac{1}{2}$ gallon.
Iodide of ammonium	2000 grains.
Iodide of cadmium	2400 „
Bromide of ammonium	1200 „

Pulverise and dissolve without heat.

Precautions to be Observed.

The proportion in which the iodising solutions are to be added to the collodion is the same in each case, viz., two fluid drachms of iodiser to six drachms of collodion; they may be employed separately, or in a state of mixture, but it is not advisable to add No. 3 to No. 1 in a proportion greater than one-fourth of the former, lest crystals of bromide of potassium should be precipitated.

At the risk of appearing prolix, I have decided on calling attention to certain minor details of manipulation, which are in themselves simple, but may be unknown to some who may yet wish to carry out the instructions contained in this paper.

Beginning with the cotton, which we suppose to have been previously cleansed by potash, it will be necessary to dry it very perfectly before using the acids, since the quantity of water which I have given in the formula is so great, that any further dilution would certainly ensure the destruction of the fibre by the nitrosulphuric acid. The cotton may be dried near the fire, or upon the steam-bath before mentioned; and, when once dried, it must not afterwards be left in a damp place.

In mixing the acids, it simplifies matters to select a stoppered bottle which holds very nearly the proper quantity of oil of vitriol when filled quite up to the neck. The nitric acid and the water may be measured in a narrow cylindrical hydrometer glass — a mark being made for the former with black varnish, at a height corresponding to one-third of the bulk of the oil of vitriol, and a second mark lower down for the water, the quantity of which will vary according to the strength of the acids. Before using these measures, always invert them, and allow the drainings from the last operation, consisting of acid diluted by absorption of atmospheric moisture, to flow out. Then measure the oil of vitriol, and make a leaden counterpoise for it in the scales, bottle included. This is necessary when perfect accuracy is desired, since otherwise the nitrosulphuric acid will be stronger in winter than in summer, which I have found to be the case to a noticeable extent—the product of pyroxyline obtained from 300 grains of cotton being fifty grains heavier in frosty weather than during the hot months of June and July. It is not absolutely necessary to weigh either the nitric acid or the water; and, with regard to the sulphuric acid, the plan which I have adopted has been to measure it as a rule, but to put the bottle afterwards into the scales, if a sudden change of atmospheric temperature takes place.

A failure would certainly be produced if the three constituents of the nitrosulphuric acid were not properly mixed; but there is no difficulty in effecting this by stirring with the broad spatula for half a minute in a shallow vessel. In the deep porcelain pots before spoken of it may not be quite so easy, and thus it is advantageous to adopt the plan which I have usually followed of mixing a double quantity of acids at one time in a jug, and pouring it afterwards into the pots. The sides of the jug, however, must not be too thick, or the temperature will sink below 150° in very cold weather, especially when the sulphuric acid is a little weaker than usual, or the mixture is kept too long in the jug.

Some persons may perhaps be inclined to keep a portion of the nitrosulphuric acid ready prepared, and to obtain the correct temperature by mixing cold acid with the hot. If so, bear in mind that a stoppered bottle must be used, since nitrosulphuric acid, like oil of vitriol, absorbs water from the atmosphere. On one occasion some experimental results were completely spoilt, by leaving the acid for a few days in a beaker covered by a glass plate; the upper part became so far weakened that, on putting in the cotton, it instantly dissolved.

Taking the temperature of the acids is an operation of some nicety, and especially so in cold weather. Begin by stirring briskly with the glass spatula in a circular direction; then dip the thermometer exactly into the centre of the liquid, and hold it in that position for at least a minute, since the rise of the mercury, although rapid at first, may be very slow towards the end. If the acid be too hot, it can be cooled two degrees, by taking a cold spatula and stirring it for a few seconds; therefore it is of consequence that the spatula which is used to immerse the cotton should be previously warmed by dipping it in the liquid. The acids also must be at least at 165° Fah. when they are first placed in the porcelain vessel, otherwise its thick percelain sides will reduce the temperature so rapidly that, although the thermometer may indicate 150° Fah. at first, it will soon fall, and the weight of the resulting pyroxyline will be greater than that indicated for a given strength of acids. In order to obtain a uniform temperature during the time that the pyroxyline remains immersed, I invert large jars upon the porcelain pots, and keep them covered, so as to prevent the cold air from blowing on the sides.

The boy who weighs the cotton into pieces of 30 grains each is directed to pull out each piece thoroughly, and work it with his fingers into a circular form, to facilitate absorption of the acid. In pursuance of the same object, each piece, as it is placed in the acid, is carefully pressed with the spatula against the side of the vessel; and in order that the last pieces may not be at the top (in which case they always come out less broken than the others), a *well* of acid is kept free by means of the spatula, and these last pieces are pushed down nearly to the bottom. When all have been immersed, the mass is squeezed against the vessel, first on one side and then on the other, for more than a minute, after which the whole is loosened by putting the spatula down to the bottom, and raising it up until the pyroxyline nearly fills the liquid; the vessel is then covered up and left for eight minutes, as before said. I think it of consequence not to finish the process of putting in the cotton by pressing it down to the bottom in a hard mass, because a good deal of solution always takes place in the acids, and this is attended with an evolution of *heat*, which increases the disintegrating action on the cotton. The object, therefore, is to prevent the mass from "heating" as far as possible, by loosening it out with the spatula and diffusing it through the liquid. Observe, however, that the cotton must not be permitted to project above the surface into the air, or oxidation and evolution of red fumes will take place. These little matters may seem unimportant, but unless they are attended to, no two portions of pyroxyline will correspond in weight.

I employ both spatulas in removing the pyroxyline from the acids, forcing them down to the bottom on opposite sides, and then bringing them together so as to pinch the mass and lift it out entire. In squeezing the acids away no time must be lost, or the action of the air may produce oxidation and red fumes. A few seconds will be sufficient, and especially so if great pains be taken to distribute the pyroxyline through the water by catching it with the gloved hand. A sensation of heat is felt at first, due to dilution of the oil of vitriol; but this soon ceases, and the chance of failure from that cause is very slight. If the material, however, were simply thrown into a small quantity of water, and allowed to remain, the rise of temperature might be sufficient to cause solution.

I was not without hope at first that the waste nitrosulphuric acid, which one scarcely likes to throw down the sink, lest it should act upon the leaden pipes, might be useful for some other process. In this expectation, however, I have been disappointed, since the pyroxyline which it contains in solution appears to interfere with its application to any such purpose as dissolving metals, &c.

I will here remark upon the importance of rejecting any pyroxyline which turns out unsatisfactorily — perhaps from the cotton having been laid on a wet board, or left too long in the acids, &c. If any such accident happened in my practice, the whole batch was at once thrown down the sink, since collodion is an expensive material, and one of too much consequence to be trifled with.

At first, I was in the habit of placing the pyroxyline in the gutta-percha washing dish immediately on taking it from the acids; but, finding that the heat and acid together gradually decomposed the gutta-percha, and made it sticky, the plan was adopted of throwing the soluble cotton first into a leaden sink, and, when the greater part of the acid had been removed by a few hours' washing, lifting out into the gutta-percha dish.

The gutta-percha washing-tray will require cleansing after a week or so; a deposit adheres to the bottom, which seems to consist of matted fibres of partially dissolved pyroxyline. This material having been some time in the water, might perhaps decompose and liberate oxides of nitrogen in collodion I am careful, therefore, not to disturb it at first; and, when sufficient has collected, it is scraped out, and the tray washed with water.

It is better not to complete the washing of the pyroxyline with boiling water, nor to use any carbonated or caustic alkali to remove the last traces of acid. All alkalies tend to decompose pyroxyline, and remove a portion of the peroxide of nitrogen in the form of nitrite; and, although I am aware that dilute ammonia is commonly employed to neutralise the acid, I have long discontinued its use, finding that some varieties of pyroxyline assume a yellow colour, and become more unstable in collodion when previously treated with ammonia.

The pyroxyline may be prepared in small quantities at a time, as required for use; but if it be necessary to keep it in stock (which I myself have never done), it should be dried either over oil of vitriol, or at a temperature below 120° Fah. Mr. Hadow mentions 140° Fah. as the point which ought not to be exceeded. Probably something depends upon the particular variety of pyroxyline; and with some kinds I have seen red fumes given off, on placing the material in a covered tin vessel surrounded by boiling water. Pyroxyline for keeping ought also to be put away in a dry place, and excluded from light, since this substance is known to be liable to spontaneous change, and unfortunately the exact conditions of permanency have not been ascertained. Having completed the preparation of the pyroxyline, this list of "Precautions" is nearly at an end: a few words on the subject of plain collodion will close it. When first I commenced the manufacture, I employed glass carboys for holding the collodion, but afterwards rejected them for two reasons: partly because the shape is inconvenient as regards the deposition of the sediment; and, secondly, the glass being sometimes badly annealed, has been known to yield to the inside pressure in hot weather. For the last two years and a half I have substituted narrow-mouthed stoppered bottles, holding two gallons each: they may be obtained of Messrs. Brown and Co. of Farringdon Street.

There is a decided advantage in placing the alcohol in the bottle before the ether, not only in facilitating the solution of the pyroxyline, but also in enabling the operator, by shaking the bottle, to remove a flocculent deposit, which otherwise is apt to adhere, and to be drawn over with the collodion; the mass of pyroxyline wetted by the spirit acts effectually as a *mop*, and cleanses the sides.

In drawing off the collodion, place the bottle in such a position that the end of the siphon comes between the eye and a strong light; any flocculi which appear likely to be drawn into the end of the siphon will then be seen, and may be avoided. When it is not intended to refill the bottle immediately, pour out the sediment and introduce half a gallon of absolute alcohol, which will absorb the remaining ether vapour, and prevent it from being oxidised into acetic acid, and afterwards forming acetic ether. On one occasion a two-gallon bottle having been used for collodion and left empty, was put away in a dark place for about three months It was then washed out with about a pint of plain collodion and refilled. The result, however, was unsatisfactory; for on adding the iodiser to the newly-made batch, it at once became yellow, which was probably due to portions of collodion left at the bottom of the bottle having decomposed and ozonised the ether. Mere washing with plain collodion was not sufficient in this case, and a thorough cleansing with shot and water should have been resorted to.

No attempt must be made to utilise the sediment of the plain collodion by redistilling the ether from it. This I have tried, but with indifferent success; for although the ether so recovered appeared tolerably good at first, it soon acquired the property of liberating iodine from iodide of potassium, and the collodion then became unfit for any purpose, excepting copying objects of still life, where extreme sensitiveness is not required.

Whilst the collodion is settling down, the bottle should be covered over, to exclude the light. The room which I used was a vault, lighted by gas; and whilst plain collodion remained in that room, it continued good; but if any portion were taken up into the glass house, and left exposed, I always found that it gradually deteriorated, colouring at once on adding the potassium iodiser, and being deficient in sensitiveness.

In manufacturing collodion in large quantities, I think that mistakes will be prevented if separate measures, scales, funnels, &c., are kept for each purpose; and in cases where two operations are being carried on at the same time—such as picking out wet pyroxyline, and filtering iodising solution—a basin of water may be placed near at hand, into which the boy dips his fingers in passing from one process to the other. The mention of matters so trivial may excite a smile; but I think that the importance of extreme method in all matters relating to photography is sometimes overlooked.

Observations on the Preceding Formula.

The distinctive peculiarity of the collodion now described is in the pyroxyline, which, by a proper adjustment of the proportions of the two constituents of the nitrosulphuric acid, acquires peculiar properties. These I need not now describe, seeing that they are sufficiently referred to in the Report of the Collodion Committee; suffice it to say, that by using the sulphuric acid much in excess of the nitric, great transparency and toughness of the film are secured, with a fine surface texture, which gives sharp definition. At the same time a quality of image is obtained corresponding closely with that produced by an organic material like gum-arabic applied to the surface of the film, and possessing a fine ruby red colour when taken in a moderately good light.

With regard to the temperature at which the pyroxyline should be made—I worked at first at 140° Fah.; but at the commencement of last spring was induced to raise it ten degrees, in consequence of representations that the collodion was somewhat deficient in fluidity. This increase of temperature, however, assists in generating traces of a body (probably nitroglucose) which causes the collodion to lose its sensitiveness more rapidly after iodising.

Some perhaps will not be prepared to believe that a sensitive pyroxyline can be made at so high a temperature as 150° Fah.: and with nitrosulphuric acid of the ordinary composition, this would indeed be difficult. When, however, the proportion of nitric acid is greatly reduced, I do not find that the sensitiveness is so much affected by the temperature of the acids.

The proportions of ether and alcohol in the collodion, half-and-half, will, I think, be found to be those best adapted for general purposes. With less alcohol the film is more contractile, and more prone to dry up after sensitising. With a larger proportion of alcohol, say two parts of alcohol of ·805 at 60° to one of ether of ·725, the sensitiveness is impaired. A friend, whose judgment is quite to be relied on, has used more than two gallons of my collodion prepared with excess of alcohol, and he assures me that it is remarkably well adapted for coating large plates, and is sufficiently sensitive for copying works of art and for landscapes; nevertheless I do not recommend this formula in preference to the other for a normal collodion, seeing that we have no means of increasing sensitiveness when it proves deficient.

I have tried the effect of varying the strength of the alcohol from sp. gr. ·805 to ·820. When the ether and alcohol in the collodion are used in equal parts, the latter must not be in what is termed the absolute state (sp. gr. ·805), or the film will be more or less impervious to liquids, like gutta percha, if the particular pyroxyline which I advise be adopted. With alcohol not stronger than ·820, the collodion works well at first, but becomes rather thick and non-adherent towards the bottom of the bottle. I therefore take an intermediate strength, by using alcohol of ·805 for the plain collodion, and alcohol of ·817 for the iodiser.

The quantity of iodide of potassium in collodion made by this formula ought not greatly to exceed 3½ grains to the ounce, or there will be peculiar markings on the surface of the iodide of silver at the lower corner of the excited plate. The purer the pyroxyline, the greater the chance of the iodide being in excess; but nevertheless, if the above-mentioned quantity should produce a film more opalescent than the operator desires, it will be in his power to give additional creaminess by introducing a little iodide of cadmium, without any danger of the iodide bursting out upon the surface and producing the marks before described.

In the Report of the Collodion Committee recently published, I think that an erroneous impression is conveyed as to the length of time this collodion will keep after iodising, which may have resulted from several members of the committee having worked in a bad light. Certainly there are some varieties of pyroxyline which displace iodide from iodide of potassium less rapidly than the pyroxyline which I advise; but there are others which do so more rapidly, and hence the position of the collodion as regards keeping properties is intermediate. It is also in our power to increase the stability, by using the mixed iodides of potassium and cadmium instead of the iodide of potassium only, after which the collodion will retain a fair share of sensitiveness for many weeks.

The cadmium iodiser has not the marked effect in glutenising this collodion which it is known to exercise with some other kinds; and when the nitrosulphuric acid is used at the weakest point possible, the resulting collodion, iodised with cadmium, will be quite manageable even on glasses of considerable size.

White spots have been spoken of in connexion with the potassium iodiser. My experience leads me to believe that they do not depend upon any insoluble particles, but are due to specks of dust adhering to the film. I find the same spots oftentimes in collodion containing only iodide of cadmium; and since the mixture of ether and alcohol given in the formula is capable of dissolving 4 grains of iodide of potassium to the ounce, it is not easy to understand how there can be any insoluble particles, when only 3½ grains are employed.

In proposing the pyroxyline mentioned in this paper as a good commercial form, I would call attention to the tenacity with which it adheres to the glass: it has been pointed out to me that the collodion, after keeping for a time in the iodised state, is well fitted for use in Taupenot's process, and does not show any disposition to rise in blisters beneath the albumen.

The principal fault which I found in this collodion during the last summer was the occasional occurrence of fine black lines, showing on the

finished picture in the direction of the dip. They are most abundant when the pyroxyline is made in rather concentrated acids; and by increasing the quantity of water in the nitro-sulphuric acid, are nearly removed. Much may therefore be expected from the use of potash as a cleansing agent to the cotton, since a weaker nitrosulphuric acid can then be employed without causing solution of the fibre.

The foregoing paper is incomplete in one point, viz., in not describing the effect of leaving the cotton in the nitro-sulphuric acid for a longer or shorter time. My experience has been, that a short immersion gives a product at least 15 per cent. heavier, but dissolving in the ether and alcohol with a larger amount of sediment, and yielding a slightly less limpid collodion.

ON GUM AS A PRESERVATIVE AGENT IN THE DRY PROCESS.

By R. W. Forster.

Observing that gum has been lately recommended as a preservative agent for dry collodion, I am induced to communicate the results of my experiments with that substance during the past summer, in the hope that they may prove useful to some of your readers.

The trouble of preparing the albumen solution for the Fothergill process, the rapidity with which it spoiled in warm weather, and, I may add, the uncertainty of the results obtained, urged me to seek some other preservative which could be readily prepared, and would keep for a length of time in working order. After trying various other substances, I found gum-arabic to satisfy my requirements best upon the whole. The strength of the solution is not very material — one ounce to ten or twelve ounces of water answers very well: by keeping a bit of camphor in the bottle it may be preserved fit for use for any length of time. I proceeded as usual in the Fothergill process; washed the sensitised plate in a *measured* quantity of water (six drachms for a stereoscopic plate), poured on the preservative solution, and washed again thoroughly under a tap.

I find this process to yield exceedingly good and certain results, though the keeping qualities of the plates appear rather limited. At the end of a fortnight in warm weather they begin to deteriorate, though in any less time I have never found any change. Probably, however, they would keep longer if the coating of gum were allowed to remain on the plate, instead of being washed off.

There is, however, one great difficulty which I have never been able altogether to surmount, but which I am convinced is in no way connected with the nature of the preservative solution employed. I allude to the appearance of what has often been described as "marbling," or "brain-like markings," in the sky and high lights, and which completely spoils otherwise good negatives. This fault is not, however, peculiar to the Fothergill process, as I have met with it in using Norris's prepared dry plates.

I at first supposed imperfect washing to be the cause, and therefore varied the method, increased the quantity of water, and took every possible precaution, but all to no purpose. That the fault was not in the developing was proved by the fact that, on carefully examining a prepared plate by daylight, the markings could be faintly seen, though they could not be detected by artificial light, or in the yellow light of the operating-room. As the bath used was newly made and in good order, nothing remained but the collodion to be examined.

The collodion I usually employ is iodised with iodide and bromide of cadmium; and as these salts have the effect of causing collodion when kept long to assume a sort of gelatinous consistence, it occurred to me that some such action might be the cause of the defect. The adoption of an ammonium iodiser was, however, unattended with any better results. I next tried varying the proportions of ether and alcohol, the addition of chloroform, &c., without much better success. I found, however, that the evil might be mitigated to some extent, though not cured, by immersing the plate in the bath as quickly as possible after coating with collodion. It should be mentioned, that though various samples of pyroxyline were tried, all were of a kind yielding a tolerably tenacious film, which was found quite needful, in order to withstand the necessary washing; for nothing, I think, can be more provoking than when you have got a good negative to see the film give way under the final washing. I next tried Keene's collodion, but found it gave a film deficient in strength, and extremely liable to wash off. That, however, was remedied by a preliminary coating of gelatine, and a few pictures were obtained free from the grand defect; but my experiments in this direction were cut short by a totally unexpected difficulty, which I have not heard of as having occurred to any one else. This was the rising of the film in blisters *during or after the washing for removing the surplus preservative solution.* The blisters disappeared when the plate was dried, but left marks of their outlines, which became very conspicuous when the picture was developed. This blistering was not obviated by the careful drying of the gelatined plates, either at the ordinary temperature or by artificial heat; nor even by strongly heating them over a spirit lamp. I have not experimented any further with regard to this difficulty; but perhaps some of your readers may be able to give an explanation of it.

From the results of these experiments I have little doubt that the cause of the "marbling" is the use of a collodion giving too strong and compact a film; yet it is very desirable to have a film tenacious enough to bear moderate washing without having recourse to a preliminary coating of the plate, which not only entails additional trouble, but a double risk of dust specks, the danger of spoiling the silver bath, and other disadvantages. The developer which seems to answer best for this process is composed of two grains pyrogallic and one grain citric acid to the ounce of water. For fixing I am uncertain whether cyanide or hypo is preferable; the latter is what I have generally used, but it is necessary to guard against making it too strong, as a saturated solution has a very marked effect in weakening the film.

NOTICES OF RECENTLY PUBLISHED STEREOGRAPHS.

The Foreign Stereoscopic Cabinet.

Lovell Reeve, 5, Henrietta Street, Covent Garden, London.

This is a happy idea, which, if well carried out, cannot fail to be popular. Instead of circulating a collection of stereographs in the book or pamphlet form, Mr. Reeve has commenced publishing a series of foreign views for the stereoscope, mounted in the ordinary way, and having the descriptive letterpress at the back of each subject—a packet of three slides, contained in an envelope, being issued every month. Of the subjects now before us (those contained in packet No. 1), the assemblage is somewhat heterogeneous, consisting of The Trade Hall at Bruges, by E. Moxham; a pent-roofed shop against the Monument of St. Ronian, in Normandy, by the late R. Howlett, entitled, A Sketch of Character at Rouen; and the Valley of the Flen, Lausanne, Switzerland, by the Rev. J. Lawson Sisson. We do not know by what process the last-named subject was taken; but, if by the turpentine-waxed paper method introduced by the operator, it testifies to the excellent definition capable of being attained thereby. The high lights are a little over-developed, producing a slightly chalky effect, but in other respects the specimen is one of a picturesque and pleasing subject, well executed. Of the other two slides we prefer Mr. Howlett's, which is artistically graphic and attractive.

There are two or three points upon which we fancy the publisher might improve. In the first place we expect that it would be more interesting if, instead of mixing together scenes from various localities, a series illustrative of a continuous tour were issued. This arrangement would be more instructive, and might be managed so as to give quite as much variety as is at present the case: architecture, landscape, and local character might all find a place; and, once "in for a journey," few subscribers would be inclined to discontinue till the close. Our next hint applies to a point of manipulation. The specimens under inspection, though otherwise well executed, are somewhat spoilt from not having been printed upon sufficiently glazed paper, which for stereoscopic slides cannot be too highly albumenised, as the offensive grain of the paper when under examination in the stereoscope is to a very considerable extent neutralised. The third defect to which we would direct attention, though a small one, and not peculiar to the specimens now under notice, is one so easily obviated that we think there are few persons who would not avoid it if their attention were drawn to the objection: it is that of cutting the proofs in an arched form at the top. This is a very common practice with many operators, because it gives a sort of finish to the slide, but is very detrimental to the effect in the stereoscope, particularly if, as in the best instruments, the subject be viewed through a rectangular diaphragm; but, under any circumstances, the arched form is a mistake for stereographs, for we are not often in the habit of seeing subjects through apertures of that form.

ON FIXING POSITIVE PROOFS.

By MM. Davanne and Girard.

(*Concluded from page* 37.)

We will now turn our attention to the fixing agent most generally employed, and to which in most cases the gradual fading of proofs is due. The hyposulphite of soda dissolved in water is employed

in various degrees of strength: we shall soon decide what degree of strength is best; but at present we confine ourselves to replying to this question — Does hyposulphite of soda leave any thing in the proof that can cause it to fade?

When a proof is allowed to remain a proper time in a fresh bath of hyposulphite of soda, experiment shows that the fixing is excellent; and analysis proves that the fixing agent has not left in the proof the least substance that can alter it, either immediately or subsequently.

But this clear and precise result is modified in a disastrous manner in certain cases, which may all be summed up in two, one of which is easy to study, while the other presents great difficulty and complexity.

We will commence with the study of the latter.

Every photographer is aware that when we take a certain quantity of a solution of nitrate of silver and pour it cautiously into a solution of hyposulphite of soda, that a white precipitate appears, which is immediately dissolved. This precipitate is hyposulphite of silver, $Ag\,O, S^2\,O^2$. It is a very unstable body, insoluble in water, and which, immediately it assumes the solid state, is decomposed into sulphide of silver and sulphuric acid, according to the formula:—

(a). $Ag\,O, S^2O^2 = Ag\,S + SO^3$

This body will combine with hyposulphite of soda (which is what takes place when it dissolves), to give rise to a very beautiful crystallised salt, slightly soluble in water, and more soluble in hyposulphite of soda, to which Sir John Herschell, who discovered it, gave the formula,

$$(Ag\,O, S^2O^2)\ \ 2\,(Na\,O, S^2O^2)$$

We obtain the same compound in a state of solution in hyposulphite of soda, when we agitate a solution of the latter salt with an excess of recently precipitated chloride of silver. This body, the properties of which have not yet been well examined, becomes decomposed immediately it is placed in contact with an excess of nitrate of silver, and conforms then to the reaction *(a)*. It is upon these two compounds that the alteration of the proof depends, in the conditions under consideration; and we can describe the latter by saying—

Every time that the fixing by hyposulphite of soda is made in such conditions that the hyposulphite of silver remains for a few moments in contact with the paper without the power to dissolve in an excess of hyposulphite, this salt will be decomposed in the sheet according to the reaction *(a)*, and, in consequence of the formation of sulphuric acid, will give rise to the decomposition of one equivalent of hyposulphite of soda.

(b). $SO^3 + Na\,O\,S^2O^2 = Na\,O\,SO^3, + SO^2 + S.$

The sulphur thus formed will be deposited on the proof, side by side with the sulphide of silver, so that not only a part of the silver covering the proof will be sulphurated on leaving the bath, but it will also carry off a second quantity of sulphur, which, little by little, will sulphurate the unattacked silver and alter the proof, and consequently make it undergo a more considerable sulphuration.

We must, therefore, occupy our attention in seeking the conditions under which these accidents can be produced. The one is accidental, the others are produced normally, when a bath is employed in fixing too great a number of proofs. We now proceed to the examination of each.

When a proof is taken out of the printing frame and immediately immersed in the fixing bath, it must be continually moved about, otherwise a considerable quantity of hyposulphite of silver will be formed in contact with the proof; and not meeting with sufficient hyposulphite of soda to dissolve it, it is precipitated and decomposed, as will be shown.

If a large number of proofs are placed in contact in the bath, without a certain interval of space between them to permit the hyposulphite of soda, when stirred, being renewed among each of them, the same accident occurs, and in this case, as in the former, the proofs will very probably be lost.

An accident of the same kind, but local, occurs when a bubble of air forms on the proof being fixed. Then the hyposulphite of soda passes by capillary attraction through the fibres of the paper opposite to the air-bubble, and forms in the substance of the paper hyposulphite of silver, which, not being dissolved, is immediately decomposed on the spot, and forms those yellow stains which photographers are but too well acquainted with.

We now arrive at the normal causes. They are due to the employment of the solutions known as old hypo baths; and we are led to inquire how these old hyposulphites act, and when they become old, or unsuited to good fixing.

The experiments we have undertaken on this subject clearly establish that a solution of hyposulphite becomes unsuited to the permanence of the proof much sooner than is generally believed, and after having fixed only a very small number of proofs it is still capable of fixing a large number of proofs; but this fixing is necessarily bad, and involves the destruction of the proof.

A few facts will make this easily understood. When a solution of hyposulphite of soda, at 10 per 100, has served to fix a proof, and has removed the salts of silver not acted upon by light, it constitutes a solution—not of chloride or of nitrate of silver in hyposulphite of soda, but a double hyposulphite of soda and silver in the same solvent. Now, direct experiment proves that the real saturation of hyposulphite of soda by means of this double salt is very rapidly attained: thus, in placing a solution of hyposulphite of soda, of 10 per 100, in contact with a great excess of recently precipitated chloride of silver, filtering the liquor and abandoning it to repose, we recognise at the expiration of a very short time that a strong proportion of double salt is deposited in the crystalline state, very pure and white. If we then seek to determine the richness of this liquor, which does not alter when exposed to the air, and which must be considered as corresponding to the saturation of the hyposulphite by the double salt, we recognise with astonishment that this solution does not contain at 60° F. more than twenty-seven grains of silver in every litre (thirty-five ounces), which corresponds to thirty-six grains of chloride of silver to twenty-five drachms of new hyposulphite. Now, we know that a whole sheet of paper contains, after sensitising, about twenty-seven grains of chloride of silver only; therefore, when a sheet and a half, previously freed from nitrate by washing in water, is passed into a bath containing a quart of hyposulphite solution of the strength of 10 per 100, the bath will be saturated with the double salt.

It does not follow from this that the bath will henceforth be incapable of dissolving a fresh quantity of chloride or nitrate of silver — far from that; it is still capable of dissolving considerable quantities, and it is in that the danger lies. For, as the crystallisation obtained in the preceding experiment indicates, and as will be shown still better in the experiments we are about to describe, the hyposulphite solution can dissolve much more chloride and nitrate of silver. It is capable of fixing many more proofs; but from the moment it is supersaturated with the double salt, it is in an unstable condition, and tends to return to the preceding stable condition, a tendency manifested by a slow but constant decomposition. The details are as follows:—

If we take a quart of a solution of hyposulphite of soda, of the strength of 10 per 100, and stir into it forty grains of freshly precipitated chloride of silver, the latter will be dissolved, and form the normally saturated solution spoken of above. If to this saturated solution we add a second, and then a third quantity of chloride of silver, equal to forty grains, these quantities will successively dissolve; but the solution will become unstable, and soon deposit, not the double white salt, but free hyposulphite of silver, which is immediately decomposed. This deposit will be slow to produce itself completely, but it will be none the less dangerous to the photographer.

The same result will take place if, instead of adding chloride of silver to the hyposulphite of 10 per 100 strength, nitrate of silver is added. In the first place, and if the quantity of nitrate is small, the hyposulphite of silver formed by precipitation dissolves, and crystals of the double salt are deposited; if, after this, nitrate is added, the liquid will dissolve large quantities of it, nearly two ounces to the quart of solution. The liquid will then have greatly exceeded the degree of saturation indicated, and also be exceedingly unstable. This point arrived at, it will decompose with very great rapidity, depositing, not double salt, but hyposulphite of silver, which, conformably to the reactions indicated in the formulæ *(a)* and *(b)*, will yield sulphur and sulphate of silver. A very abundant precipitate will form in the course of a day, and the supernatant liquor will contain not more than one ounce of nitrate of silver to the quart of bath. At the end of three days that quantity will be diminished three-fifths, and continue to diminish day by day until it reaches the point of saturation indicated above.

We will now endeavour to explain these facts, which it is easy to do. The double salt $(Ag\,O, S^2\,O^2)\ 2\,(Na\,O, S^2\,O^2)$ is dissolved to saturation in hyposulphite of soda. We first add a small quantity of chloride or nitrate of silver; these, more soluble in the hyposulphite than the double salt, dissolve; they then form a new quantity of double salt, which is precipitated in a white condition, as there is nothing to dissolve it. We then add a fresh quantity of one or the other substances: this reacts on the double salt, which is precipitated, or rather is precipitated by a slow action, and decomposed—

a fact easily proved, for experience shows us that by taking pure and white crystals of double salt, it suffices to add to them an excess of soluble salt of silver for a decomposition to take place, sometimes slow, sometimes rapid, according to circumstances, which is manifested by a deposit of hyposulphite, as indicated by the following formula :—

$$(c) \left\{ \begin{array}{l} (S^2\,O^2, Na\,O)^2\ (S^2\,O^2, Ag\,O) + 2\,Ag\,O\,Az\,O^5 \\ = (S^2\,O^2\,Ag\,O)^3 + 2\,Na\,O\,Az\,O^5 \end{array} \right.$$

the hyposulphite of silver, moreover, decomposing according to the formulæ *(a)* and *(b)*.

NOTES OF A PHOTOGRAPHIC TOUR IN THE HOLY LAND.

No. XIV.

Nazareth lies in a ravine that falls through the hills to the plain of Esdraelon, the level of which is about three miles distant. This great plain, of which I have before spoken, especially at Haifa, which is on its western coast, runs, in fact, completely across Palestine, from the sea to the Jordan. The plain is a very uniform level from north to south, with a slight ascent from the Mediterranean eastward to the foot of Tabor. This is the summit of the water-shed, and from this it falls eastward to the Jordan and Sea of Galilee. The north side of the plain is thoroughly walled up by almost precipitous hills, which are the last falling off of Lebanon, of which the high peaks commence twenty miles to the northward. One of the bluffs overlooking the plain is the traditionary Mount of the Precipitation, where Christ was led out to be cast down. I think there is not much faith to be placed in the tradition, especially as that hill was in the city, and this is three miles distant.

But from any one of these hills around Nazareth there is a glorious view, and you may well imagine that I have not found eight days too many to drink in the enjoyment of the views of Galilee. From the hill near the tents I have taken views of Cana, Safêd, Tabor, Endor, Nain, Jezreel, Gilboa, Shunem, the Plain of Esdraelon and its various villages, the river Kishon, and Mount Carmel beyond, with the peaks of Lebanon towering in the north, and Mount Hermon, white and glorious, standing in the north-east like a sentinel guarding the Land of Promise, and looking down into the depths of Genesareth, which lie to the eastward, but are not visible from here.

You will scarcely care to hear of the Convent at Nazareth, which was built on the alleged site of the Virgin Mary's House. Many of these places pointed out by the monks are worthy of credit, while others are so manifestly without authority, that to place any confidence in them implies a total submission to the statements of tradition, even in the face of reason. The house of Mary is no longer here. It departed through the air to Loretto, in Italy, a long while ago, pausing on its way somewhere in Greece for awhile. But the grotto under the Church of the Annunciation is curious and worth visiting, ornamented as it is with the gifts of royalty through many centuries. It opens by broad steps up to the floor of the church. Descending these you are in the shrine, and on the spot where the angel met her with the first "Ave Maria." How she came to be in this cavern does not precisely appear; but there is a vaulted passage leading from it to the place which was the kitchen of her house, and it may be that this explains her being in the cellar when the angel came.

The attendant monk pointed out a broken column, the upper part of the shaft hanging from the wall above, and he seemed to think there was something miraculous in it.

I hasten to leave this place. I have nowhere in the Holy Land been more disgusted than I was here with the attempt to locate the events of the life of Christ.

Was it not enough that on these hills the Boy wandered? that His young feet learned here those first tottering steps that led Him afterwards up and down the hills of Syria, a houseless wanderer, without place to lay His head, until He bore the cross up the ascent to Calvary, and they laid His head at last on the rocky pillow hewn for Arimethean Joseph? Was it not enough that this blue vault that overhangs Nazareth once covered the glory of God on earth, and sustained the clouds of countless angels looking down on that sublime mystery, in which they had no part, and of which they had no adequate conception? Was it not enough that here He learned, in accents of this earth's language, to speak that word "mother," hallowed for ever after, a thousandfold, that His lips have spoken it so often, so tenderly, from childhood until His last sad bequest to John the Beloved, at the Cross?

It is an evening of exquisite beauty. The stars shine gently, lovingly, on Nazareth. The picture of the valley from my tent door is exceedingly beautiful. A group of tall and graceful women are filling water-jars at the Virgin's fountain. The other tents are silent. No one moves. The wind rustles the leaves of the olive trees, but there is a hush in the very sound. Selim and Benish-dad lie side by side on the ground, profoundly still. You would think them dead men, such is their perfectly motionless attitude.

Our invalid has been somewhat stronger this afternoon, but toward evening she seemed to fail a little. She has expressed a longing desire to see the shore of Genesareth, and we are very anxious to remove her there if she rally sufficiently to bear the motion. I fear that she will never hear the "music of Galilee's waves" on earth. But there are more musical waters in that country to which she goes. God help us! What pilgrims we all are! D. T.

Meetings of Societies.

LONDON PHOTOGRAPHIC SOCIETY.

An ordinary meeting of this society was held on Tuesday, the 6th inst.,—P. Le Neve Foster, Esq., M.A., in the chair.

The minutes of the last meeting were read and confirmed.

After some conversation it was determined that the proceedings should commence with the adjourned discussion upon the Report of the Collodion Committee.

Mr. Heath: Sir, I have a very few observations to address to the meeting upon this question, but as I moved the adjournment of the report, I venture to believe that it may be conformable to the wishes of the meeting that I should commence any observations which should be made upon the discussion.

I have no doubt I shall thoroughly carry the feelings of the meeting and of the committee with me, when I say that I think the acknowledgment of our gratitude is due to Mr. Hardwich for the assistance he has rendered to the collodion committee in particular, and to the society at all times. Not only has Mr. Hardwich taken infinite pains and trouble in the matter—not only has he for their purposes, as we hear, unreservedly laid before Mr. Malone his formula, but his experience and time have been at the command of every member of the committee; in fact, he has done that which he has always done upon all occasions where the interests and progress of photography are concerned. I am anxious to make this acknowledgment because I feel it necessary to take exception to the Report of the Collodion Committee. Let me be quite understood. I do not in the least question the high character of Mr. Hardwich's collodion; in point of fact I am prepared to make the admission that it merits the very highest commendation. Nevertheless I do seriously doubt whether it was wise, or just, or equitable, that that report should have been made at all. Sir, it will be remembered that, at our meeting in this month of last year, a letter was read from Mr. Hardwich asking for the appointment of a committee to report upon his formula for collodion. It will be remembered, also, that at the same meeting the Secretary stated what was the intention of the council with regard to that proposal; and, if I am not mistaken, the same gentleman who presides over us this evening, in answer to a question by Mr. Shadbolt, who had asked for an explanation (he having detected some difference of opinion as to the proper functions of the committee), said as follows:—"He was not aware that Mr. Hardwich entertained any objection to the form of resolution proposed by the council." — (therefore it appears that there was a difference between the proposal of Mr. Hardwich and the resolution of the council.) "The committee would be formed for the purpose of considering any collodions or formulæ for making them which individuals and manufacturers may desire to lay before it, not confining themselves to the one collodion of Mr. Hardwich, but taking a broader basis of operations." Now I turn to the first paragraph in the report of the committee, and I find it there stated, "that Mr. Hardwich, Mr. Mayall, and Mr. Sutton, had sent collodion, but that the two latter gentlemen had not sent sufficient to admit of its being thoroughly tested. Hence, although individual members of the committee had worked with the collodions of Mr. Mayall and Mr. Sutton, the committee in its collective capacity could only pronounce upon that prepared for them by Mr. Hardwich." Sir, it does appear to me that if the committee was formed for the purpose, so clearly and plainly defined by the Chairman, of testing the various formulæ sent in to them by the various manufacturers, and if that purpose could not be carried out, either by failure in sending in formulæ or otherwise, the existence of the committee was at an end — practically it was defunct. Let me reason the question in this way:—A committee was formed at Manchester for testing the various dry and preservative processes; — we recollect the printing committee here; — and very lately the Photographic Society of Scotland, had a committee for testing lenses. Now, supposing each of these matters had been the secret of an individual, I ask, would those committees have been justified, if only one process or one lens had come before them, in publishing a report stating that this process or that lens was the best?—would it not be manifestly unfair and unjust towards others? And yet that is what you are asked to do by the adoption of the last paragraph of the report. The stamp of the approbation of the society is a thing most desirable to be obtained—it is an

honour and a privilege dearly to be coveted; but I hold that a scientific society should well weigh the full consequences of affixing its seal of approbation to anything that may come before it. I have no hesitation in saying that, in consequence of the publication of this report, Mr. Hardwich's collodion will rank in the estimation of the public as superior to that of any other manufacturer. Now, is the society prepared to take upon itself the perpetration of this act of manifest injustice? If so, there will not be a maker of collodion without just cause of complaint. I speak from an experience, based upon the opinions of a vast number of people, and I am taught by that that there are many collodions which can compete successfully with that of Mr. Hardwich; and the observation I have to make now is certainly the most important that I can offer to your notice—it is that, in dealing with this question, you must bear in mind that Mr. Hardwich's collodion is a commercial article, that it is made for sale just as much as Mr. Thomas's or any other maker's. Now it is this commercial element to which I must beg to keep your attention, when I ask you, in the interest of all makers of collodion, not to give a sort of preferential authority to Mr. Hardwich's collodion, because other makers have not thought it consistent with their interests to come forward and lay before you their formulæ. I notice, sir, and I must admit the notice caused me very great regret, that in a foot-note at the end of the report of the proceedings of the last meeting we were referred to an advertisement from Mr. Hardwich, in which he stated his intention to discontinue manufacturing his collodion for sale. Now, I really have no right to interfere with that which is a gentleman's private and individual business, but I do most sincerely regret that determination. I do not comprehend the necessity for his withdrawing from the manufacture of his collodion, simply because it may be said, as I say now, that it is a commercial article. Let his collodion compete on fair grounds with other makers' collodions, and no one will have any right to complain. Now it is because this collodion is a commercial article that I object to the expression contained in the report of its merits; and it may be a bold assertion to make in this room, but I do say, that when members of this society who form a committee come forward with a report which gives a certain preference to this collodion, I, as a member of this society, have a perfect right to come forward and say upon my experience that there are other makers whose collodions are superior. I scarcely know whether it is right, but I, at all events, will not use this society for the purpose of mentioning particular names; though I think I may venture to state my own experience with the collodion of one maker during last summer (I will be particularly guarded in not mentioning names), and I only refer to it because I think that if a report of this nature is to be made and adopted in the transactions of the society, the experience of myself and others should take their places by the side of it. I have by my business engagements but little opportunity to practice photography; but I think some time in February of last year I took home twenty ounces of collodion, and between February and November I may have taken perhaps a dozen pictures. I think I may probably be able to show negatives taken within that time which shall be deemed satisfactory—at all events, whether I worked in March or November, the exposure given to my plate—making of course an allowance for the difference of light and temperature—was as nearly alike as possible. I mention this for the purpose of saying that I cannot help thinking that a collodion of this nature must be far more serviceable and valuable in the hands of all, but especially in the hands of amateurs who only work occasionally, than a collodion which so speedily loses that quality which is so essential, namely, its sensibility; and I must ask you just to bear in mind this fact when you are legislating upon the question—accidentally I use the word legislating, but I think I am right, for your decisions come to in this room are rules of guidance for those who are not present, and, therefore, if the society say that a collodion of a particular maker is of superior excellence (for those are the words used), I think that is clearly laying down a rule for the guidance of those who are not present.

I have a very few more words to add, and I sincerely apologise for having kept you so long. I regretted to notice that only two-thirds of the names of the committee were attached to that report. I have the greatest respect, I may say, the greatest admiration for the names of the committee who have signed it; nevertheless, I think that I should have felt less strongly upon the question, and others would decidedly have felt less strongly, if the names of the other members of the committee had been there also; and, probably, I am somewhat influenced in my opinion by knowing that one gentleman who was on the committee, and whose name is not attached to the report, agrees with me in my opinion with regard to the value of that particular maker's collodion I have just referred to. I do not mention his name, for I am quite sure the meeting will credit my assertion. The gentleman alluded to is very highly respected, and a most careful and painstaking manipulator. I think, if the committee had looked at the matter, and merely judged it in its business bearings, that they would have hesitated before presenting a report upon one collodion, when the committee was formed for the investigation of a number of collodions.

With regard to Mr. Hardwich himself, I trust that he will see that the few remarks I have made are founded upon good, sound, and logical reasoning; at all events, if I fail in convincing him in that, I trust I shall not in this;—that the necessity I have felt for making these observations does not in the least affect the very high estimation in which I hold Mr. Hardwich for his productions, and the great services he has rendered to photography

Mr. Sebastian Davis: Sir, I think there is a very tangible reason why a report should have been given upon Mr. Hardwich's collodion, and with that impression I venture to make a few remarks upon the subject. It may be in the recollection of some few members that it was determined that no report should be given, and no collodion examined, unless it were accompanied with a full and detailed account of the formulæ for making it. Now, I conceive it would have been quite possible for Mr. Thomas to come forward, or any other maker, if he had wished, and describe his formulæ. If I understand the question, we are here a body of gentlemen met for scientific purposes, and it is upon those scientific principles that we investigate and are called to decide upon the different formulæ. It certainly seems to me that as only one collodion was placed in the hands of the committee they were compelled, in justice to the gentleman who prepared that collodion, to give a distinct report. I think, therefore, it would have been an act of injustice to Mr. Hardwich to have refrained from giving an opinion upon his collodion after examination.

Now, passing from this question, let us consider the collodion itself, its manufacture, and its properties. Taking the general report, I am inclined to think that it may, without doubt, be considered to be very good as regards its adhesion to the glass and the easy way in which it flows over a large-sized plate. I have tested some which Mr. Hardwich has been kind enough to forward to me, and it has this advantage; and I think we have thus gained a great point, because, undoubtedly, all those experienced in collodion must know that it is most difficult to arrive at a satisfactory formula in that respect.

Now, passing to the use of iodide of potassium in iodising collodion, I think that iodide of potassium alone is not the best salt for iodising collodion; the reason for which is apparent, and is, that iodide of potassium in solution is more prone to decompose the ether and alcohol in collodion than any other of the salts in use except iodide of ammonium. Iodide of potassium has, generally speaking, when prepared in a pure condition, an alkaline reaction; now if we add ether to it we shall find the decomposition taking place without the addition of the pyroxyline. If, on the other hand, we make an iodising solution of a different kind, the mixed fluids remain colourless for any length of time. I do not think that the iodide of potassium alone produces a sensibility equal to that of other collodions which may be purchased in the market at the present time. I think that the committee have made two or three anomalous statements. They assert, in the first instance, that the collodion in sensibility is unsurpassed; and they state also that Mr. Frith, at a temperature of 130°, was enabled to take moving figures with this collodion; but I remember a remark he made in this room, when he returned from the East, that he found his own collodion too sensitive, and that he had to counteract that by adding acid to his bath. If you take portraits in a medium light, you will find that the evidence of gentlemen is contradictory as to Mr. Hardwich's collodion in preference to others. Mr. Delamotte says he has found Mr. Hardwich's collodion very sensitive. Again, Mr. Williams and Mr. Morgan, I think, and some other gentlemen on the committee, state that in portraiture they do not find it so sensitive, but conjecture that this may perhaps be accounted for by the employment of citric acid in the developer. Citric acid in the developer! Why, a collodion to be tested against another collodion must be tested under precisely the same circumstances, and in this instance I have no doubt this was done. I bring forward these facts, not with reference to Mr. Hardwich's collodion in particular—no one has a greater respect for that gentleman than I have, and this society and the photographic art are indebted to him for his formula, freely given to us all—but I think that there has been, up to the present time, no published formula given for collodion equal in sensibility to those known sensitive collodions which may be found in the market. I trust that the committee, which is still in existence, may receive some assistance by which this one point may be got over, and then it will be in the power of all members to make their own collodion, or have a practical knowledge of how a collodion can be made; and the experience they obtain in making it will be a great benefit to them, and they will gain in scientific knowledge by the investigation of this interesting subject.

Mr. Delamotte: I should like to correct the last speaker in something he has just stated. I think that the report which I sent in was not quite fairly quoted by Mr. Davis. In the report I believe I remarked that I should wish, if possible, that the collodion might last for a longer time in the iodised state. I did not complain of any want of sensitiveness in the collodion when I first used it.

Mr. Sebastian Davis: I referred to the sensitiveness of the collodion after it had been mixed, say three weeks in the summer. My own conviction is, that a collodion may be made very sensitive by using a different iodising compound.

Mr. Watson: I am happy to find that we have come to a more thorough knowledge of Mr. Hardwich's formula than formerly; because, when the resolution for the appointment of this committee was come to, I find by the Journal that Mr. Sebastian Davis stated "that he had, within the last week, carefully examined the formulæ given for the manufacture of pyroxyline in the last edition of Mr. Hardwich's *Manual*, and found that, with the materials he had used, instead of obtaining a satisfactory pyroxyline at the temperature stated, the cotton dissolved more like

lump sugar than cotton; and it appeared that the recommended quantity of oil of vitriol was decidedly in excess. He merely stated this to show why it was desirable that when gentlemen communicated details, they should have an opportunity of defending themselves. He knew full well that many communications had been made to the society by gentlemen, and yet other gentlemen with a considerable amount of photographic knowledge had not succeeded in following out their views, although they appeared to be exceedingly explicit and clear. Therefore, he for one would advocate the appointment of a working committee to test the particular formula laid before the meeting. Under those circumstances, there must be a full and clear and precise description of the whole process, from the beginning to the end, so that any other operator shall be able to succeed in the same manner, because it was known that science was based upon exact principles, and all must arrive at the same result." Now, it seems that Mr. Davis has no difficulty at the present time with the formula; therefore he must either have misunderstood it in the first instance, or have received further information, and it is desirable that this should be clearly explained. On looking over the report I do not find that the committee have taken the trouble to examine any formulæ. There is no formula stated of Mr. Sutton or others. They might have ascertained whether by the formulæ given they could have made the collodion similar to the samples sent in. Now, I should like to read to the meeting what was stated as being the decision of the council; and this will be found in the last March number of the Society's Journal:—"The secretary stated that the council had considered Mr. Hardwich's proposition, and resolved that a committee of the society should be appointed to examine and report on the various formulæ for making collodion; and that members of the society and makers of collodion be invited to send samples of collodion, such samples to be accompanied by a statement of the manner of their manufacture." Now, we have had no report of that description. Mr. Davis is not singular in being unable to produce a collodion from the formula which was sent in. I have heard more than one state that they have tried and failed. I have heard one gentleman, who is second to none in London as a practical chemist, say that he cannot make collodion of any description by the formula. I think that the collodion of other makers might have been accepted under the same condition as Mr. Hardwich's, inasmuch as his formula was not examined.

Mr. Hughes: Query.

Mr. Watson: There is no account of such examination.

The Chairman: May I call your attention to the last paragraph but one, to the effect that Mr. Malone has examined the formula in its chemical aspect, and is satisfied with it.

Mr. Watson: That was not in the first report sent round to the members. [This was a mistake of the speaker, which elicited the general dissent of the meeting.]

The Chairman: I do not know of any report but that which appeared in the Journal.

Mr. Watson: Well, there was another sent out; and I want to know at whose expense these slips of paper which are circulated among the members are published?—whether at the society's expense, or at the expense of the party about to read the paper?

The Secretary: From the first establishment of the society it has been customary to send round a slip to the members of the council, and to such gentlemen as might probably take part in the discussion. The type having been already set up for the Journal there is only the expense of pulling the proofs. [The Secretary appeared to be about to continue the explanation, but was stopped by a sudden burst of applause.]

Mr. Watson was about to further argue this matter of expense, when Mr. Shadbolt rose to a question of order.

The Chairman said: I did not like to interfere, for I thought the gentleman would not be very long, and that we might lose time in endeavouring to stop him.

Mr. Watson: With respect to the latter part of the report, the committee state that the collodion which they have examined is superior; but they do not say to what it is superior, and superior is a comparative term—scarcely, I think, a proper word to use, seeing that they had nothing to compare that collodion with. If they had examined the other samples—if they had made collodion from the other two formulæ sent in—they might then with propriety have stated that this collodion was superior to the others.

Mr. Morley: It really appears to me (begging the gentleman's pardon for interrupting) that we should understand the matter better if the formulæ alluded to were brought before us. I therefore move that Mr. Hardwich's paper be now read.

Mr. White seconded the motion, which was duly put and carried.

Mr. Hardwich then, at the request of the Chairman, read his paper [see page 76], and afterwards stated that an error had crept into it which he wished explain. He had worked for more than a year with one thermometer, but before reading his paper he thought it desirable to ascertain whether this thermometer was correct. It appeared, on comparing it with another and more expensive instrument, that it was five degrees too low all the way down the scale, from 170° to 100° Fahrenheit. To be quite sure, however, he had afterwards sent the instrument to an eminent optician, who compared it with his standard thermometer, and wrote back to say that it was remarkably correct, even to the fraction of a degree, and that the other thermometer must have been wrong. The temperature at which he worked would therefore be correctly stated at 150° F., instead of 155°.

The Chairman: It is my duty to invite discussion upon this paper of Mr. Hardwich's; but before the discussion begins, I have to announce that Dr. Becker has been unanimously elected an honorary member of this society.—(Applause.)

As no one rises, I will take the opportunity of saying a few words with regard to a paper Mr. Sutton has sent to be read this evening. He imagined that this would be an evening in which we should have an opportunity of reading it, and he was anxious that it should be inserted in the Journal, and afterwards to have a discussion upon the subject at our next meeting—the subject being Mr. Sutton's New Panoramic Lens, of which you have a specimen on the table.

Mr. Heath: Having, sir, made the remarks which I did at the commencement, I shall intrude myself upon you for a very short time. I may be permitted now to say, I owe it to Mr. Hardwich that I should propose that the best thanks of the meeting be given to him for the paper which he has read. I look at that paper in a totally different light from the report; and I do think our thanks are due to Mr. Hardwich, as they would be to any other gentleman who might come into this room and give us his advice and assistance. Mr. Hardwich has done this upon all occasions, and he has again done it in this laborious and painstaking paper. It is gratifying to me now to move that the best thanks of the society be voted to Mr. Hardwich.

Mr. Watson seconded the motion, which was duly put, carried, and acknowledged.

Mr. Heath: May I ask, now, whether it is supposed that the report of the collodion committee is taken and adopted?

The Chairman: I do not know that it is adopted by the meeting. The report is received, and the meeting has expressed its views. I do not think that there is any adoption by the society generally.

After the chair was vacated, Mr. Malone stated that he and several members of the committee had come to speak in defence of the report, but the Chairman said it was then too late.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

An ordinary meeting of this Association was held at Myddelton Hall on the 29th ult.,—George Shadbolt, Esq., Vice-President, in the chair.

The minutes of the previous meeting having been read,

The Chairman called on the members to nominate officers for the ensuing year.

Mr. Legg recommended that a record of the attendance of each member of the committee should be furnished next meeting, to guide members in voting. Agreed to.

In the absence of the gentleman who was to have read a paper, Mr. Barber read the following letter from Mr. Oakeshot, of Ryde:—

Ryde, *February* 15, 1860.

Dear Barber,

I see by The British Journal of Photography, received this morning, that you presided at the last meeting of the North London Society, and that the subject of discussion was a paper, read by Mr. Hughes, on the *Alkaline Gold Toning Bath*, particulars of which, I suppose, we shall have in next number of the Journal. I observe, also, that Mr. Hardwich was present, and that, in his remarks, he stated he had used one fixing bath of hyposulphite of soda all through last summer. On reading this, I was not a little surprised to find that no one present called attention to the experiments of the French chemists, MM. Davanne and Girard, on this very point.

These experiments, if correctly given, seem to me all important, as they appear to throw especial light on that annoyance to photographers—the gradual change of paper prints; and they will perhaps, in some measure, explain why certain prints seem permanent and others transient, when, according to appearance, all were treated alike.

Messrs. Davanne and Girard assert positively that a quart of hypo solution of ten per cent. in strength will fix only one and a half sheets of paper; this in plain figures means, if my calculation be correct, that four ounces of crystallised hypo will only just fix ten pictures, $8\frac{1}{2}$ by $6\frac{1}{2}$; then this number of prints will saturate the above quantity of hyposulphite of soda with hyposulphite of *silver*, and if more than this number of prints be passed into the same solution, there is a certainty that an injurious element will be left in the paper, and, sooner or later, infallibly destroy the print. Can not you, at one of your meetings, call attention to the subject, and have it a little ventilated? I fancy that most photographers expect more work out of hyposulphite, even when new, than (if these chemists are right) it seems able to give. I noticed also, in the same number of The British Journal of Photography, a letter from Mr. Hardwich, about economically working the alkaline gold bath, by precipitating the unused gold with protosulphate of iron. I manage mine more simply than that. Instead of reducing it by iron, I leave it to reduce itself as it likes, and use the same solution over and over again, merely adding a little fresh gold with each fresh lot of prints, and occasionally also a little more carbonate of soda. I find this plan answer quite as well as making a new lot each time; the inside of the bottle becomes gradually coated with a black deposit of gold, which can be easily recovered again by dissolving it in a little nitro-muriatic acid. I do not think I have anything more in particular to say just now. I shall look anxiously into the journals to see what some of the great guns in photographic chemistry have to say about the Frenchmen's notes on Fixing. I shall be glad to learn your idea about it. I hope you are preparing for a photographic trip, and, should you chance to come this way, I will do my best to give you welcome.

Yours truly,

Mr. J. Barber. C. OAKESHOT.

Mr. Hughes said that Mr. Oakeshot greatly misunderstood Mr. Hardwich's observation. Mr. Hardwich used an almost saturated solution of hyposulphite of soda rendered alkaline—not for six months, or for any stated time, but he added continually fresh crystals of hyposulphite of soda, thus constantly renovating it; and as a proof of its freedom from sulphuretting action, an old bath of this kind would not *tone* a print, even if it were left in it for some considerable time. It was a common fault to use a solution not sufficiently strong to fix the prints. This fault might be recognised by looking through the print, when it would be found to be covered with measly spots in the fabric of the paper, which did not occur when a strong or weak solution was used newly mixed.

With regard to the second part of the letter, he thought, judging from the colour of the deposit on the bottle, that it was owing to the presence

of oxide of silver, and expressed an opinion that as much would be lost as gained by the repeated use of the same gold solution, owing to the increased rapidity and extent of decomposition.

Mr. Barber inquired whether a black deposit appeared in the hypo bath by keeping?

Mr. Hughes said there was nothing but what might arise from dirt—nothing resembling a black sulphide of silver.

In reference to the appearances presented by prints which had been imperfectly fixed,

The Chairman thought Mr. Hughes in error in stating that the measly spots were only to be found when using an *old* weak fixing bath; he had purposely experimentally produced them with fresh hyposulphite. When he first noticed those singular marks which Mr. Hughes had called "measly" spots, he had fancied from their yellow colour that they might be sulphur; but this was not the case, as he had found them totally unattackable by bisulphide of carbon, which, had they consisted of sulphur, would most assuredly have dissolved them. He did not attribute them to chloride of silver left in the paper, but rather to some compound formed with the partially dissolved starch with which the paper was sized. He had found that, when once these measly spots had formed, placing the prints in even a saturated solution of hyposulphite of soda would, so far from removing them, only tend to increase their extent.

Mr. Hughes agreed with the Chairman that the spots were not chloride of silver. He thought it probable that they were to be attributed to a too dilute bath, and had some experiments in progress with a view to ascertain the minimum strength at which the bath could be employed without the spots making their appearance.

Mr. D. W. Hill thought it unadvisable to use the gold bath over and over again—that when properly managed the amount of gold left was very minute. If a small number of prints were to be toned a less quantity of gold might be employed, and if it toned too slowly it might be warmed.

Mr. Dawson, on being asked to give the result of his experience, said that the process used by him was identical with that of Mr. Hughes, and that Mr. Wilson, of Aberdeen, used it also, the only difference being that Mr. Wilson used fresh hyposulphite, while he (Mr. Dawson) used a saturated solution, which he kept neutral by the addition of chalk, great care being necessary in warm weather, or when the bath is exposed to heat, he having found an alkaline bath to become acid in ten minutes on one occasion, when he had placed it on a stove. When the hypo bath is kept it should be in a cool place. He thought a large quantity of gold was wasted by some operators, and considered that by warming, half might be saved. Mr. Wilson, of Aberdeen, used fifteen grains for toning thirty or forty prints. He (Mr. Dawson) dissolved fifteen grains of chloride of gold in a gallon of water, and added as much carbonate of soda as would cover a sixpence: in cold weather he warmed it on a sand bath, and found it would tone four hundred stereoscopic prints. Papier Rive would not give black tones, but with Saxe paper any degree of blackness might be obtained.

The Chairman said that one important subject had not been alluded to—that was washing: he considered that most people washed their proofs for far too long a time, and that one hour was sufficient if they proceeded upon correct principles. In taking the prints out of each quantity of water, he hung them up to drain till nearly dry before putting them into fresh water, and continued changing till the last drop from the corner ceased to have a sweet or metallic taste.

Mr. Hill, being pressed for time, suspended his prints in a deep vessel, turning the tap on them, and drawing off the water from the bottom by means of a siphon; he left them all night.

Mr. Shave said that the evils of long washing were admitted, and mechanical means had been suggested to obviate them.

The Chairman thought that mechanical washing had been proposed more with the view of saving trouble.

Mr. Dawson had never observed any change to be produced in prints toned by the alkaline gold process by any length of washing, although he had in those toned by the old hyposulphite of soda. He agreed with the Chairman that the washing might be accomplished in much less time, provided that care were taken to prevent the prints from sticking together. He placed, say one hundred stereoscopic prints in a dish holding two or three gallons of water, stirred them round well, then drained off the water closely, and repeated this six times. He then changed the water two or three times in the next two hours, by which time he considered that the hypo was effectually removed.

Mr. Hughes said some other fixing agent than hyposulphite of soda might be found: he did not think the resources of chemistry were exhausted. It was comparatively a short time since hypo was first used by Sir John Herschell, who was still living.

The Chairman had with others successfully used ammonia, but it was very unpleasant to manipulate with.

Mr. Dawson said ammonia removed the albumen.

The Chairman said it did not do so after the latter had been coagulated with nitrate of silver.

Reference was made to M. Humbert de Molard's fixing with cyanide of potassium saturated with iodine. Also to the different colours of gold deposit.

The Chairman announced that, in accordance with the rules, the officers for the ensuing year were to be nominated at the present meeting, for election at the annual meeting on the 28th March.

The names of several gentlemen who had been nominated to serve on the committee were then handed in.

Mr. Hare exhibited a very portable binocular stereoscopic camera, the body of which collapsed, on the bellows principle, the focussing being effected by means of a screw, and the bottom of the camera serving as the top of the tripod stand.

The Chairman exhibited some stereoscopic slides of *Fountains Abbey*, &c., by Mr. Woodward, of Nottingham.

Several members regretted that these well-executed specimens had not been taken with a bi-lens camera, it being evident, on a very casual inspection, that they were not.

Mr. Shadbolt also exhibited some stereoscopic illustrations of a collection of five hundred gems, ancient and modern, by Mr. Rodgers, of Montrose, and some other subjects by the same operator. These were much admired, and several present noticed the peculiar pseudo-scopic effect produced by viewing the representations of the gems upside down.

The meeting, after assuming a conversational character, was then adjourned to the 28th instant.

MANCHESTER PHOTOGRAPHIC SOCIETY.

A meeting of this Society was held on the 7th instant, at the Rooms of the Literary and Philosophical Society, 36, George Street,—Mr. Parry in the chair.

The Honorary Secretary read a letter which he had received from Mr. J. A. Forrest, of Liverpool, stating that the Liverpool Society of Fine Arts had decided to open in April next an exhibition of works by eminent ancient and modern artists, among which was to be included an exhibition of photographs, and asking for contributions from the members of this society: the Liverpool Society would bear the expense of carriage.

Mr. W. T. Mabley presented five large and very beautiful photographs to the society's portfolio, taken by the collodio-albumen and wet collodion processes.

The Hon. Secretary also laid upon the table a print from a negative taken by the panoramic lens, and which was presented by Mr. Samuel Cottam to the society's portfolio.

A vote of thanks was passed by the meeting to Mr. Mabley and Mr. Cottam for their donations.

The Chairman exhibited several very beautiful paper negatives taken by him about six years ago, which were much admired for their sharpness, &c.: they were on Canson's plain paper, and waxed afterwards. He said the process was one of the ordinary ones; but if any member wished for particulars of it he should be very happy to give them. He (Mr. Parry) hoped that more attention would be given to waxed-paper, as he believed the process to be capable of more than was generally supposed. He intended to give it a trial next summer.

Mr. Sidebotham exhibited a very compact stereoscopic camera, which was very much admired for its lightness, construction, &c.; also a very convenient form of bag for changing plates in the field. He then called the attention of the meeting to the fact that one of their members (Mr. James Mudd) had obtained the prize medal at the Exhibition of the Photographic Society of Scotland, for the best photographic landscape. He thought it was a subject of great congratulation to them, particularly as it was taken by the society's favourite dry process—collodio-albumen. Mr. Mudd's picture was one of several of his which had been much admired at the exhibitions both of London and Edinburgh for their great beauty: the Manchester Society had cultivated this process with great success, and had a long time since issued a report on its superiority over all other dry processes, by a committee specially appointed to test the relative merits of the various processes.

The Chairman remarked, that Mr. Mudd had been requested by the Photographic Society of Scotland to read a paper on the collodio-albumen process, and had written one which was read at their last meeting, and he (the Chairman) thought the remarks made upon it by one of the members of that society very uncalled for.

Mr. Mudd, in explanation, said that the reason he had spoken in his paper of *introducing* the process to the Photographic Society of Scotland, was because, on looking over the catalogue of the society's exhibition, he found that the collodio-albumen process was only represented by one member of that society (a lady), and consequently he concluded that if they happened to know it in theory, they evidently did not in practice.

In reply to a question, Mr. Wardley said he had once been successful in developing a collodio-albumen plate with sulphate of iron, but on subsequent trials he did not again succeed.

Several other members said they had only been able partially to succeed in developing collodio-albumen plates with iron.

The Chairman stated that in the process of etching steel at their works they obtained occasionally very large crystals of proto-nitrate of iron, which will keep some time in the crystalline form. He had given some to Professor Crace Calvert, who had expressed great surprise, and promised to give his opinion respecting them.

Mr. Mabley said it was quite unknown to chemists for the protonitrate of iron to remain in the form of crystals more than a very short period.

The Chairman promised to bring some to the next meeting.

Mr. Sidebotham exhibited some very beautiful stereoscopic transparencies, taken on plates which he said were easily prepared, and rapidly

printed and developed. His experiments with the process by which he had produced them had been, so far, very successful; but he preferred waiting until the next meeting, and making further trials before giving the process publicity.

The Secretary of the society brought the subject of the Photographic Exchange Club before the notice of the meeting. He had now nine names down, and should be glad to receive any others. Non-members were equally admissible with the members of this society. A committee would be formed to carry out the club. Any negative above the size of half-plate to be admissible; or, if members of the club liked to contribute stereoscopic pictures instead of large ones, two stereoscopic pictures would be considered equal to one large photograph.

After a very agreeable and interesting meeting, the proceedings closed with a vote of thanks to Mr. Parry for his services in the chair.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

At the monthly meeting of the members of this society, held on the evening of Tuesday, the 28th ult., Mr. Haines in the chair,

Mr. W. B. Osborn, one of the Vice-Presidents, delivered an address

On the Serio-Comic Aspect of Photography.

He remarked, that so much had been said or written on the subject of photography as to make it difficult for one to say anything new about it; but, as far as he was aware, the aspect in which he was about to view photography had never been made the subject of a paper. It frequently happened that that which was a very serious matter to a photographer, appeared essentially comic to a looker-on. When a young man, for instance, taking a fancy to photography, purchases his instruments and chemicals, and forthwith proceeds to take likenesses of all his friends and of everything within his reach, including his cat and dog and the nearest brick wall, the energy with which he goes to work is amazing. But in a little time he begins to experience a disappointment here, and a failure there, and finds that matters do not go on so smoothly as when his apparatus was new. The blunders he is making cause him much anxiety, and are, of course, a serious matter to him, though to the looker-on they simply suggest how comical it is that a young man should bother himself so much about anything of the kind. But the advanced photographer is sometimes no better off. Having carefully prepared a number of dry plates, and gone a long journey in search of the picturesque, and brought home (as he thinks) a number of beautiful transcripts of scenery, it is intensely comic to watch his serious expression when he finds his developer develops nothing but a lot of spoiled pieces of glass. Then every one knew how comical it was to come in contact with "the unfortunate photographer." He is always in trouble. He never can manage to take any picture whatever. He has either over-developed or under-developed; over-exposed or under-exposed: he has either neglected to keep his plate in the bath long enough, or forgotten to put it in the bath at all; or, if he goes out, ten to one but he has forgotten his bath, or taken with him an empty collodion bottle, or dropped his developer by the way. But, as if to compensate for these mishaps, nature has produced "the universally successful photographer." He never has a failure, and spends half his time in letting the photographic world know it, though, singularly enough, he and the photographic world usually hold different opinions on the point. There is also "the enthusiastic photographer," who is always going to do some wonderful thing, but never does it; and the "grumbling photographer," who never can take a picture himself, and can never see a beauty in the pictures of anybody else—who sees too much shadow here, and too much light there, and who usually forsakes the practice of photography altogether in disgust, saying that it is unworthy the notice of any one having the least taste for art. The "curiosities of photography" were another source of serio-comic study. What endless portable tents that were not portable, unless with the assistance of a man and boy! What huge mistakes in the shape of developing boxes! What wonderful cameras, which were almost to take pictures by themselves! What demonstrations that unless you use the very last lens out there is no use your attempting to take a picture! A great deal of this was pure humbug. He (Mr. Osborn) did not see that they had very much improved upon the old lenses. As for baths, he did not see why their old gutta percha friends should be discarded altogether because glass baths had been brought out, liable as these were to break and lose half-a-gallon of solution. A writer in one of the journals was for making every photographer an amateur mechanic, and, if he succeeded, the dealers in photographic stores would probably pass him a vote of thanks; for as soon as a man commenced dabbling in amateur mechanics, so sure was he to spend double the amount that he might get the same article for from a respectable house, and the result would be nothing but disappointment. As connected with the serio-comic aspect of photography he (Mr. Osborn) spoke of the gin-and-water process, the raspberry-syrup process, — the former of which, he thought, was liable to the objection that "it won't keep." One of the serious aspects of photography was the extent to which it was followed as a business on Sundays, and the lecturer expressed a hope that the various societies throughout the kingdom would endeavour to put down the practice. In conclusion, he narrated some amusing adventures which had happened to himself and friends in their ardent pursuit of photography under difficulties, forming a fitting close to the series of serio-comic sketches.

The address occupied nearly an hour in the delivery, and of course the above report is a mere summary of the leading points.

On the motion of Mr. Brown, seconded by Mr. Ball, a hearty vote of thanks was passed to Mr. Osborn, and the same compliment was paid to the chairman.

CITY OF GLASGOW AND WEST OF SCOTLAND PHOTOGRAPHIC SOCIETY.

This newly-formed photographic society held its first ordinary monthly meeting on Thursday, the 1st instant,—John Kibble, Esq., president of the society, in the chair.

The Chairman delivered a very beautifully conceived and chastely expressed inaugural address, on the present position and prospects of photography.

Mr. A. Mactear, one of the Vice-Presidents, read a paper *On the History of Photography in Glasgow.*

A discussion ensued on the conclusion of Mr. Mactear's paper, in which Professor J. Taylor, Messrs. Kibble, J. Spencer, sen., J. Stuart, Ewing, Hugh Wilson, J. Cramb, &c., took part.

The Secretary announced that Messrs. Cramb Brothers had been successful in producing photographs on ivory, not artificial but real ivory, and laid untouched specimens, and others highly finished in colours, on the table for inspection, and which were handed round and much admired. Mr. Cramb intimated that for the present the manner of production would not be disclosed.

The meeting, which was a large one, seemed fully to answer in the affirmative the question, "Was a photographic society required in Glasgow?"

Exhibitions.

PHOTOGRAPHIC EXHIBITION AT LIVERPOOL.

We beg to remind intending exhibitors at the forthcoming Exhibition of Photographs in connexion with the Liverpool Society of Fine Arts that contributions should be delivered to the London Agent, Mr. James Bourlet, 10, Foley Street, Portland Place, W., not later than the 19th instant; or at the Exhibition Rooms, Queen's Hall, Bold Street, Liverpool, not later than the 24th instant. Mr. J. A. Forrest, 58, Lime Street, Liverpool, will gladly supply any further particulars required.

As no exhibition of photographs has taken place in the "capital of the North" since 1854, the coming display is looked forward to with much interest by all admirers of the "new art," and also by those who take an interest in art generally. It is to be hoped that the rapid progress made in the photographic art, during the eventful six years which have elapsed since the first and only exhibition held at Liverpool, will be distinctly marked by the pictures forwarded for the approaching exhibition.

ARCHITECTURAL PHOTOGRAPHIC EXHIBITION.

[BY OUR SPECIAL REPORTER.]

A visit to this exhibition confirms an opinion that has been growing upon us for some time, that architecture is the field in which photography displays its greatest strength and power. In the microscopic detail, in the strength and transparency of the shadows, and in the faithful delineation of every variation in texture, colour, and form of the object represented, we have a combination of artistic qualities denied to the artist of the pencil. Then the sober hues of the subjects, and their limited range of colour, render architectural photographs more faithful than those of other objects.

The value, to the professional architect, of such a collection as that now exhibited, must be beyond all calculation; while to the amateur or mere photographic collector, it must possess an interest, arising as much from the subjects as from the fidelity of representation which the mode of producing them secures. This exhibition displays an advance in excellence upon that of last year. Manipulation in photography has become, comparatively, so certain in its results, that the photographer has had more leisure to cultivate the artistic element of his art, and he has well improved the opportunity. At length justice has been done to the architect as well as to his work; and in these views, so intelligent, as a rule, in their recognition of the resources and capabilities in *chiaroscuro* of the noble originals, we are glad to forget the bald representations by untutored photographers of former years.

We must not be thought wanting in patriotism if we say that the artistic element is most conspicuous in the productions of our Gallic neighbours. Messrs. Bisson Frères, in our judgment, bear the palm. By their long experience in this department of art they have gained great mastery, and their noble views of *Strasburgh*

Cathedral are alone sufficient to make us exclaim enthusiastically, "We, too, are photographers!" These views forcibly recal the sensations of delight and surprise we experienced at witnessing the wonders of the diorama painted by the creator of photography, Daguerre. Pity it is that he did not live to see these triumphs of the art to which he gave birth! They are truly dioramic; thus distinguishing them from the productions of the artist or the engraver. Architectural drawing was fast disappearing, when photography flashed upon us with the new power imparted by collodion, and now, we think, few artists would be bold enough to enter the lists in competition with the photographer.

The photographs in this exhibition are judiciously classed by countries, although the various nations are very unequally represented. France and England are greatly in the majority, as might have been expected: next follow Spain, Rome, Venice, Jerusalem and its neighbourhood, Constantinople, Germany, Switzerland, and the Netherlands.

We feel impelled first to notice the comparative merits of the various photographers whose works constitute this collection. And here we are again struck with the strong individuality each photographer can impress upon his works, which is quite as marked and distinguishable as the style and touch of the painter. Beside the works of the artists already named, those of Messrs. Cundall and Downes stand in close relation, from similarity of subjects and artistic excellence. Their *Views at Rouen* are worthy of the subject, displaying true artistic feeling and a full appreciation of the capabilities of the object. The *Views in France*, by the French artists, are interesting from variety in the subjects selected. The *Tower of St. Jaques de la Boucherie, Paris*, and the *Hotel de Cluny*, are exceedingly interesting. Not less so, but from a very different cause, are the *Ruins of the Roman Theatre at Arles*, the *Palace of the Popes at Avignon*, and the *Walls* of that city, a curious specimen of mediæval fortification, now utterly obsolete. Rich and rare, as specimens of Gothic architecture, are the portals of the *Cathedral of Rouen*, of *Chartres*, of *Notre Dame de Paris*, *Bourges*, *Amiens*, and the *West Front of Saint Ouen* at Rouen. The *Staircase of Francis the First at St. Blois* is a very striking architectural picture: the staircase is external, full of bold relief, in shafts, balustrade, and panels.

Next in order comes the *Doorway of the Cathedral at Berne*, also by M. Bisson; it is an exceedingly interesting subject, exhibiting a combination of French and German styles.

Jerusalem and its Neighbourhood is depicted by Messrs. Robertson and Beato, forming an exceedingly rich collection. There is the *Village of Bethany*, looking very much like a deserted village; the *Walls near Akra*, the *Damascus Gate*, the *Sion Gate*, and the *Tower of David*—with all of which we seem as familiar as with the public buildings of London, so accurately and picturesquely have they been described by travellers. As photographs, they are truly excellent. The points of view are chosen with much tact, and are very suggestive in such views as the *Wailing Place of the Jews*, part of the old walls of the Temple looking stern and chill, while the narrow street ends in a brief vista, suggestive of a ray of hope. There is a *General View of Mount Scopas*, upon which the eye might dwell, actively occupied, for an hour. The rock tombs of *St. James and Zacharias* are highly picturesque. Among the striking pictures of this series is the *Mosque of El Aksa and the Mount of Olives*, with the two gloomy cypresses standing within the quadrangle. This is a very remarkable picture. There are several pictures illustrating the Mohamedan localities of Jerusalem, which possess too much merit to admit of their being passed by unnoticed; in fact, they are deserving our highest meed of praise. There is a series of eleven views of Constantinople, by the same artists, very interesting with respect to subjects, and very excellent as photographic pictures. The *Fountain of the Sultan Selim* seems as if it had grown on the spot at the command of some magician.

Mr. Macpherson contributes six views of Rome, very charming and interesting, making us wish there were more of them. We must, however, specially single out *Ruins of the Baronial Stronghold of Nepi*, which is a most exquisite gem of photography—so bright and clear, yet so deep and rich in tone and colour. The subject possesses very great interest, and has had full justice done to it by the artist.

The most important to many in point of interest, but the worst in execution, are the views in North Italy, by Signor Ponti. The Signor has either much to learn in manipulation of the art or he has adopted a vicious system of developing, which gives his pictures a cold, dry, opaque aspect.

Mr. Clifford contributes a few Spanish scenes, but so few as to be quite tantalising. A country so rich in architectural beauties should have been more liberally represented at this exhibition. His *Temple of Diana at Merida* is the best of his contributions, so very superior to the others, in fact, that we wonder how the same artist could have produced them.

Among the English scenes the productions of Mr. Melhuish, Mr. Robertson, and Mr. Cade, stand conspicuous. Mr. Robertson's fifteen views of *Ludlow Castle* will form a rich addition to the architect's portfolio. Mr. Melhuish's view of the *High Street, Oxford*, is the best we have seen of that subject. Mr. Cade's *Hengrave Hall* is a very excellent picture; and his series of *Lichfield Cathedral*, and of *Haddon Hall*, place him in the first rank of photographers.

Practical Instructions on Coloring Photographs.

By Alfred H. Wall.

CHAPTER VII.

The principles which guided you in the use of black and white only are just as necessary for your practice in using colours, and I therefore hope you will not neglect the instructions contained in the last chapter. But although the gradations of colour are quite as delicate and imperceptibly soft and harmonious as those of light and shade, still there is this great difference, that while in the one case you merely strengthen or weaken the single tint in use, in the other every change is not only a change in the quality of light or dark, but also a positive change in tint or colour. Now, in changing the tone of a colour, or in any way altering its character, it is important to keep all your hues, whether nearly pure or frequently "broken,"* clean and fresh. You must therefore, in mixing your pigments, select such as will not only produce, by mixture, the requisite tone, tint, or hue, but you must be careful to mix such only as blend kindly together, so as to produce a clean and pleasing result (to assist you in doing this, I gave in a former chapter a full description of all the pigments more commonly used, with their peculiar qualities in reference to this aim). When, however, the peculiar effect desired cannot be obtained by merely mixing the pigments, one is hatched or stippled over the other. For instance, should you desire to preserve the purity of a delicate colour, and yet subdue its brilliancy, you will secure this by hatching over the same with, say blue, because certain minute but undetected portions of the colour over the whole surface retain their original purity, although an equal portion of the same is subdued, and two colours which would not work kindly together when mixed in solution are thus harmoniously blended without muddiness or manipulatory difficulty.†

If you have adopted the plan of these instructions, you ought now to possess some knowledge of the scientific theory of colour, of the chemical and working properties of your pigments, of the principles which rule the practice of our best artists, and of the importance of light, shade, and reflections. You ought to know how to preserve the truthfulness of a photograph, how to strengthen and increase their more prominently artistic qualities, how to wash (don't joke), how to hatch (pray don't), and how to stipple—consequently we may at once commence practice with water-colours.

THE PHOTOGRAPH.

Select a good one. Don't let it be a flat, white-faced image; but tell the printer of that same specimen to produce you a faint delicate picture, with as little black as possible, and with all the gradations of shade unaltered. Of course the printer will look at the negative before he promises to produce such a proof; but if the negative be satisfactory, he can do it with a little care and the use of a little wool; and your persuasive power must make him say he will.

A pale warm grey is the best colour for the print, and it can be got with ease on both the plain and the albumenised paper. The whites should be as pure as they can possibly be preserved. It should be mounted, with gelatine or thin glue, on good stout London board, and (unless you have a machine yourself) sent to the hot pressers to be rolled (not *hot* pressed).

* Colours are said to be broken when mixed, or, in other words, not pure.
† This remark is equally applicable to "glazing," in oil.

The author of the preceding paper, in order to render his communications of greater practical value, has kindly undertaken to criticise the work of students in colouring, and to give them advice through the medium of these pages; for which purpose specimens may be sent, with a stamped and directed envelope *for their return, to* A. H. WALL, Esq., 11, THE TERRACE, WALWORTH.

G. A. HILL.—The specimens are good, and at the prices named would, I have no doubt, procure you employment. Your only mode of proceeding would be by advertisement or personal application. The black and white chalk specimen is a novelty; but a better effect might be got on a rougher surface with less labour.

CHIAROSCURO.—You must begin with a much fainter touch; the lines are too decided, the hatching much to angular; the back-ground may be left untouched if it is of a colour similar to your touched figure. Any amount of artificial light may be obtained by the aid of various coloured screens, and a looking-glass placed obliquely to the light. See Chapter II., and a paper read by myself at a meeting of the South London Society.

J. B., Cheltenham.—Your question is of so business-like a character, and so purely of a private nature, that you should have enclosed your address for a written reply. With our worthy Editor's kind indulgence, however, I may just add that I will undertake to tint them for you in exchange for the landscape specimens, if the latter are good. Send your address.

ANABEL.—See the answer to "Chiaroscuro."

ANOTHER STUDENT.—The colours too pure, giving a raw and bleeding effect to the flesh, and the effect is altogether too hard and wooden-like. See reply to "Chiaroscuro." I cannot add more until the subject of water colours has been fully treated.

R. L., AMATEUR NO. 2, ROSE, ALMA.—I must trouble these correspondents to read the replies given to "Chiaroscuro" and "Another Student," and the maxims given in a former chapter.

AN ARTIST.—The name (rightfully possessed) will always prove a safe passport to my sympathy. The varying phases of hope, despondency, satisfaction, discontent, and despair, are, in the course of every true artist's experience, so acutely felt, and so little understood by the good folk outside our little circle, that a fraternal bond of kindly and considerate feeling ought always to unite us, and I really think does so, despite occasional appearances to the contrary. In common fairness I cannot occupy the valuable space of this excellent Journal with the lengthy advice you require, but I will give it you personally, or, if you send me your address, by letter. Perhaps I shall be able to aid you in procuring specimens to practise upon.

A BEGINNER.—See my remarks upon the preparation of the photograph.

Foreign Correspondence.

Paris, March 10, 1860.

The Abbé Despratz has resumed his essays on collodion, which have been interrupted during the past year by indisposition. He dwells upon the instability of every kind of collodion, no matter how much its unchangeableness may be vaunted. The most apparent characteristic of the spontaneous change collodion undergoes is a diminution of sensibility. Feeble during the first few weeks, it at length becomes more decided, so that the production of a portrait becomes almost impossible. Besides loss of sensibility, time effects another most serious inconvenience in loss of tenacity in the film. Every kind of collodion appears finally to lose much of its tenacity, becoming so rotten that the film breaks up in every direction, and leaves the glass in the sensitising bath. Sometimes a collodion of good quality, when first made, will continue to give unexceptional pictures so long as the film is in the wet state, but as soon as it dries, it appears full of holes, and mottled all over.

Almost every collodion assumes, in course of time, an amber tint, which becomes deeper and deeper, even if kept in perfect darkness. This discolouration proceeds, it is supposed, from a quantity of iodine being set free. Therefore it is recommended to neutralise this free iodine, either with a few drops of ammonia, or by immersing a piece of zinc in the collodion. This expedient slightly weakens the amber tint, but never restores the olive oil colour it possesses when first prepared.

The loss of sensibility may vary greatly in different samples, even when prepared according to the same formulæ, and with the same care; but still, after the lapse of time, the sensitiveness will almost entirely disappear: we know of no means of restoring it. It is of no use endeavouring to turn such collodion to account by giving longer exposure, for it gives only a weak, indefinite stained picture on the plate. A collodion in this condition appears to have lost a portion of its iodide, gradually separating from its original combination to form a new one, which gives rise in the nitrate bath to a compound less photogenic than iodide of silver. For, if a few drops of iodised alcohol be added to such a collodion, it again becomes capable of giving vigorous proofs, at least for a time.

Tenacity can be restored to very old collodion by the addition of a certain quantity of pyroxyline.

The holes and streaks that sometimes appear in very old collodion are often due to the alcohol and ether used in its preparation being insufficiently rectified. When the rectification is properly conducted, the spots and streaks are much later in making their appearance—sometimes several months, but they finally show themselves in case the ether and alcohol are nearly absolute. It is only a question of time, but it may be stated as a general fact; for, up to the present day, we have never met with a sample free from this defect. Is it too bold a surmise to say that the continuous reaction of the constituent principles of collodion at last results in the formation of a little water?

M. Nièpce de Saint Victor has favoured us with a further instalment of his researches on light. This time it is the action which electricity, either alone or combined with light, exercises when it renders substances in the state of aqueous solution capable of reducing the salts of gold and silver. If the elements of a single galvanic pile are put into a cold solution of nitrate of uranium, this yellow salt is changed into a green salt, which, according to M. Peligot, reduces the salts of gold and silver.

A cold solution of tartaric or citric acid, in which the same galvanic elements are placed, also reduce chloride of gold.

If the platina-conducting wires of an electric pile are plunged into red wine, the wine changes in colour, becomes more alcoholic, and, if sparks are eliminated in the wine, it acquires an empyreumatic taste.

White wine, containing much sugar, submitted in like manner to the electric current, loses all its sugar, and becomes much more alcoholic: this result is the reverse of that produced by the agency of light.

But it is remarkable that all these solutions quickly lose by agitation the property of reducing the salts of gold and silver, or by a long repose in the open air: the green salts become yellow again.

We will now note the effects produced by electricity and light united. If a slightly acid solution of nitrate of uranium with the elements of a single pile placed in it be exposed to light, the liquid becomes troubled, and a violet precipitate is thrown down, mixed with subnitrate of uranium. The liquid reduces the salts of gold and silver very energetically. This violet precipitate, which is formed only under the influence of light and electricity combined, resembles in colour and properties the colouration produced by the action of light upon a sheet of paper impregnated with nitrate of uranium, which paper loses the colour it has acquired after a time, if kept in the dark.

This violet precipitate is turned green by potassa; and with an acid it resumes its original colour, and is eventually dissolved. If the elements of a simple pile are placed in a solution of oxalic acid and nitrate of uranium, or of the yellow oxide of uranium of commerce (uranate of ammonia), a disengagement of electricity naturally takes place in the dark; but if the apparatus be exposed in a white glass vessel to sunlight, bubbles of gas (carbonic oxide) will be liberated, causing an ebullition, if slightly agitated, and the force of the electric current is greatly augmented. If the oxalic acid be in excess—as it must be for the pile to act long—oxalate of zinc is formed at the bottom of the vessel. The action of the pile is not necessary for the solution of oxalate of uranium to produce a disengagement of oxide of carbon, under the influence of light, but electricity increases the action of light, as light augments the action of electricity. Neither electricity alone, nor heat (at least, if it is not above 212° F.), can produce a disengagement of oxide of carbon in the solution of oxalate of uranium. According to his experiments, light changes the nature of oxalic acid in the same way that it renders absolute alcohol very sugary, and reduces its strength several degrees; whereas, under certain conditions, electricity converts sugar into alcohol. J. P.

TO OUR AGENTS AND READERS.

In consequence of numerous applications the number of this Journal published on the 1st of January last (being No. 103), lately "out of print," has been reprinted, and may be obtained either direct from the Publisher, or through the London, Provincial, Colonial, and Continental Agents of the Journal.

Correspondence.

☞ **We are at all times willing to assist our Correspondents to the utmost of our ability, but we can only do so through the medium of the Journal. We cannot give private replies except to personal friends.**

RECOVERY OF SILVER FROM A SPOILED NITRATE BATH, &c.

To the EDITOR.

SIR,—Will you please to inform me of a means to recover the silver from a nitrate bath which I have spoiled in the following manner:—Owing to the bath fogging, I added a saturated solution of carbonate of soda, until there was a slight deposit, then filtered, and put it in a glass dish, within a pan of water, to boil for awhile. Having to leave it for a few minutes, on returning I found the dish had split, and that the whole contents were as black as ink, with a dense deposit, a part of which I enclose you. The pan was coated with tin and full of common water.

Answers to the following will likewise oblige:—

2nd. To recover the silver from old pyrogallic developing solution.

3rd. To recover the gold from old hypo and gold baths, and from old bath by Mr. M. Lyte's formulæ; with a ready method to convert the same into chloride again.

Having, from time to time, seen the clear and straightforward manner in which you answer those needing your help, I have been induced to send you the above.—I am, yours, &c.,

ONE OF THE THANKFUL.

[We have roughly examined the powder sent, and find it to consist of metallic silver, oxide of tin, organic matter, and chloride of silver. Your best plan will be to boil it in one ounce of nitric acid diluted with four ounces of water, in order to dissolve out the silver and the organic matter: oxide of tin, and chloride of silver will be left behind, the latter being present in small quantity. The nitric acid solution of the silver will be very impure, and must be precipitated by salt. If you have any large quantity of the chloride, it may be reduced by means of zinc, but if the quantity be small, it will be better to throw it into the hyposulphite fixing bath, to be separated as sulphide, by means of sulphide of potassium, when enough has accumulated.

2nd question.—Waste developing solution will reduce itself, if we may be allowed the expression. You will find the metallic silver at the bottom of the vessel.

3rd question.—Procure sulphide of potassium at an operative chemist's, and add it to the fixing and toning bath, as advised in the last number of our Journal. Treat Maxwell Lyte's bath with sulphate of iron, by a process recommended in the last Journal but one.—Ed.]

TRANSPARENT STEREOGRAPHS.

To the Editor.

Sir,—In printing glass (transparent) positives for the stereoscope, and where it is intended that one surface shall be grey (or ground), is it usual to print them on that plate of glass which has both surfaces polished, in which case the picture is necessarily inverted—right for left—except when viewed through the greyed surface? It appears to me that, by coating and printing on either the greyed or plain surface of *the greyed glass*, that this inversion might be avoided. I have had a dozen transparencies sent me, *all inverted.*—I am, yours, &c., T. G.

[Instead of contact printing, those specimens produced by aid of a lens can be done upon either the upper or under glass without inversion. The objection to printing on the smooth side of the ground glass consists in the ground side (which is then outwards) being soiled by handling, so as to display offensively the finger marks. M. Ferrier, whose stereographs are so highly valued, prints upon *plain* glass, and produces the effect of ground glass by means of a subsequent coating of pure wax dissolved in ether, or a spirit varnish *chilled* in drying.—Ed.]

BLACK STREAKS.

To the Editor.

Sir,—I observed in reading the report of the "Collodion Committee," that some of the members speak of "narrow black lines in the direction of the dip." I have met with these when using collodion by various makers, but more frequently with Mr. Hardwich's. I attribute them to a quantity of the nitrate bath collecting above the plate on the dipper, which, while draining, runs over the surface of the plate after detaching it. The remedy is simply to elevate one corner of the plate in withdrawing the plate from the bath, bringing it out diagonally, so as to allow the solution to run along the top and off at the lower corner.

I noticed that these streaks always commenced at that edge of the plate which was uppermost in the bath.

Can you inform me why, having taken in the Society's Journal from the commencement, I have not received a copy of M. Joubert's picture so long promised?—I am, yours, &c. D. W. HILL.

5th March, 1860.

[We believe that the distribution of the promised plate has been delayed by the unfavourable state of the weather for printing.—Ed.]

A "TRICK" IN PHOTOGRAPHIC PRINTING.

To the Editor.

Sir,—Your critic of the Photographic Society's Exhibition passes the bounds of his vocation when he accuses me—or gives currency to the accusation, which is the same thing—of producing effects of atmosphere by a "trick."

The courtesy which one gentleman extends to another should have prompted him to give me credit for common honesty sufficient to prevent my attempting so gross a fraud.

I cannot do more than offer to show the negatives to any one doubting the truth of my pictures.

I trust you will be able to find space for this note.

I am, yours, &c. LYNDON SMITH.

Leeds, March 2, 1860.

[We are personally responsible for the critique complained of, but cannot perceive any reasonable ground of complaint. We quote the passage *verbatim*:—

"We have been told that the aqueous-looking atmosphere does not exist in the negative, but that it is an effect produced in the printing by what has been decried as a 'trick.' We do not perceive, by the way, the justice of such a designation. If it be a 'trick' it is a clever one, though in our opinion in the instances cited carried to an unreasonable and detrimental extreme; with somewhat less of straining after effect, the operation, whatever it be, might be very probably beneficially applied."

The above is the assertion of a *fact*: we were told what is stated, and by more persons than one; but more, we objected to the designation "trick," and even defended the practice, as the above extract shows.

Our correspondent's assertion is undoubtedly quite sufficient, without the *experimentum crucis* proposed.—Ed.]

THE PREPARATION OF ALBUMENISED PAPER.

To the Editor.

Sir,—For some time I have felt a desire to add fluoride of sodium to my chloride solution, used in preparing albumenised paper; but delayed in consequence of seeing in a contemporary that fluoride of silver would not be formed on the paper by this method, but must be produced by the addition of fluoride of silver to the sensitising bath.

As I am no chemist, I wish to learn from you whether the addition of fluoride of silver would add to the sensitiveness of the albumen paper? and also how fluoride of silver can be easily made? if it will dissolve easily i the nitrate of silver bath? &c.

Can you help me to get a real ebony black in my albumen prints? I have brown, violet, slate black, &c., but not pure black.—I am, yours, &c.

A READER FROM THE FIRST.

Glasgow, February 29, 1860.

[Unless you are very expert in chemistry and photography, we advise you to have nothing whatever to do with the fluorides. Fluoride of sodium in the paper would certainly form a portion of fluoride of silver during the sensitising; but this compound being soluble in water, would tend to dissolve out into the bath, and not to remain entirely in the paper.

Fluoride of silver has been used in the negative nitrate bath, and is said to give extreme sensitiveness in some states of collodion; but it is a substance of doubtful utility, and very prone to cause universal decomposition on applying the developer to the film.

With reference to the "ivory black" on albumenised paper, it may be obtained by the alkaline gold toning bath (but only on some kinds of paper), and by printing deeply from an intense negative. Buy paper from four or five different makers, and try a sheet of each: if the fixing bath has been some little time in use, so much the better for the ebony black tints.—Ed.]

ANSWERS TO CORRESPONDENTS.

R. G.—Yes! the same.

Isis.—It is an old process revived.

Querist (Leamington).—Apply to Murray & Heath, Piccadilly, London.

Economist.—By one of Derogy's patent lenses. See advertisements.

Dubious.—We have *some* hope of M. Joubert's process,—none of the other you mention.

L. L.—We cannot tell how that particular collodion is made. You must risk your money, and abide by the result.

Otway.—The mauve colour is obtained from coal tar, and so are many other beautiful pigments. They are quite permanent.

Green-hand.—Make your glass house as large as convenient, and avoid cross lights It need not be an expensive arrangement.

Samuel G.—Positive printing by development is all but obsolete. You will find it very difficult to succeed with it.

Tom Tucker.—For a young beginner you are in too much haste. You must serve your apprenticeship to photography as well as to any other craft.

F. S. W.—We do not see anything amiss in either of your negatives, as evinced by the prints sent; we rather prefer the *bracket* of the two, but both are very good.

T. C.—A little ammonia would be an improvement in your plate-cleaning liquid: it serves to remove grease, which alcohol, not being a solvent of fats, sometimes fails to effect.

T. A. Bedford.—You must take your chance if you send them: we can promise nothing till we see them. We always act with strict impartiality to the best of our knowledge and belief.

F. S. W.—We find the following formula to succeed as a negative developer:—Sulphate of iron, ten grains; glacial acetic acid, thirty minims; water, one ounce; or in place of the glacial acetic acid, Beaufoy's acetic acid, one-and-a-half drachm. It will be occasionally necessary to intensify the image with the ordinary pyrogallic acid mixture and nitrate of silver.

J. W. Y.—Study the paper on collodion which appears in this number. The formulæ for the preparation of the bath, given in the various manuals of photography, are generally to be relied on; but do not omit to buy *the best* nitrate of silver, or all will go wrong. Twenty minims of glacial acetic acid, with one grain of pyrogallic acid and an ounce of water, will answer your purpose as a developer.

S.—White glass certainly. In your glass room described, there is *not* enough glass. The part opposite to the sitter should be of glass, both top and side, but especially the top. The place occupied by the sitter will do of wood, as you have arranged. Opaque glass is very objectionable: clear glass, with blinds, for occasional use, are far better. Remember that you want to vary the direction of your shade according to circumstances: for instance, the more prominent the features of a sitter, the more you require the light to be in front, and *vice versa.*

Received.—J. K., Rev. A.M., Israel Holdsworth.

*** Several interesting articles, some in type, are unavoidably postponed for want of space; amongst them the continuation of Mr. Grubb's series "On the Optical Centre," and Mr. Forrest's paper "On Glass;" also Professor Roscoe's lecture "On the Measurement of the Chemical Action of the Solar Rays."

☞ *All* Editorial *Communications*, Books for Review, *&c., should be forwarded to the Editor*, GEORGE SHADBOLT, 2, *Upper Hornsey Rise, London, N.*

All Advertisements *and* Letters *on the* Business *of this* Journal *should be addressed to the* Publisher, 32, *Castle Street, Liverpool.*

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 115, Vol. VII.—APRIL 2, 1860.

A very interesting observation has been recently communicated, through the pages of a contemporary, by Mr. F. Maxwell Lyte, a gentleman whose name is deservedly familiar amongst photographers, from the numerous suggestions of acknowledged practical value which have emanated from him, as well as for his skill as a photographic manipulator. It not unfrequently happens that alleged facts of an extraordinary character are asserted in the most positive manner without any real foundation; and this occurs, not from any want of good faith in the promulgator, but arises rather from incapacity for correct observation: it therefore becomes a matter of considerable importance, in order that a surprising assertion shall meet with ready acceptance, that its sponsor shall be one of known ability and integrity — such, in fact, as is the case in the present instance.

The curious phenomenon which Mr. Lyte has recently recorded, is the effect of a low temperature in materially reducing, or altogether destroying the solvent quality of hyposulphite of soda, as regards the haloid salts of silver, thereby rendering it inert as a fixing agent for positive proofs upon paper. The strength of the solution of hyposulphite of soda employed is not mentioned; but it is stated by Mr. Lyte that, during the very cold weather which prevailed in the middle of last February, proofs immersed therein, instead of becoming fixed, suffered from a double decomposition, by which sulphide of silver became deposited in the interior of the paper—in fact, that the proofs were disfigured by what Mr. Hughes, in a paper recently published in these columns, termed *measly spots.* That the effect was due to lowness of temperature appears to be pretty conclusive, as the *same solution*, on being again heated to a temperature of between 60° and 70° Fahrenheit, fixed pictures perfectly. This will probably throw some light on several hitherto unexplained failures.

At the last meeting of the French Photographic Society, M. Bertsch gave a simple and lucid explanation, in a popular form, of the defects necessarily dependent upon the employment of an uncorrected condensing lens in an enlarging camera, as adopted in the instrument known as the solar camera. To this objection we made some allusion some time back when treating of the camera in question, simply pointing out its effect without entering into details of the cause: we shall, therefore, in an early number, place M. Bertsch's communication before our readers. Judging from the excellent specimens of photo-micrography, the production of this gentleman, which we have seen, we have little doubt that he is well acquainted with microscopical manipulation, and it is consequently not at all surprising to us that he should take the same view of the solar camera as we do; in fact, it would be quite impossible for any one who has had much experience in working with the microscope to fail in perceiving that, in the enlarging camera, no novelty of principle whatever is involved, and that, in the particular construction before alluded to, needless errors of practice are introduced. In his communication, M. Bertsch offers a suggestion relative to the addition of a concave lens of glass of the same dispersive power as the condensing lens, in order to restore parallelism to the rays prior to their being allowed to pass through the negative to be enlarged, so that the two are arranged somewhat after the manner of the object lens and eye lens of an opera-glass. An instrument upon this plan is in course of construction for M. Bertsch, and we shall be glad to learn the result of a trial of its operation; but we fear that the gain anticipated by the condensation of the light in this manner will be almost balanced by the loss from absorption by the glass and reflection at the four surfaces. The idea is, however, certainly an ingenious one.

We have not unfrequently been applied to for an explanation of and remedy for the existence of a foggy-looking spot in the centre of the plate, when taking negatives of landscapes with a portrait lens, with the diaphragm between the parts of the combination. As the season for active operation in the field is now fast approaching, it may not be amiss to take the question into consideration at the present time, particularly as we observe that a correspondent of our elder contemporary, the *Journal of the Photographic Society*, offers, in the last issue of that publication, a supposed explanation, which he regards as perfectly satisfactory, but in which we certainly do not concur. This gentleman supposes the offensive spot to be an *image* of the aperture in the diaphragm, which he thinks is sufficiently demonstrated by the fact that the form of the spot corresponds with the form of the aperture as observed by altering the shape of the latter, and also that the position of the diaphragm affects the sharpness or definition of the spot. The reflections of light at the various surfaces of the lenses, as supposed by this correspondent, who adopts the designation "Onward," are quite insufficient to account for an *image* of the aperture in the diaphragm, though it is just possible that they might explain the existence of a *shadow* of the diaphragm. The case cited of the number of images of a lighted candle seen when a portrait lens is pointed towards it, is not analagous, the position of the object (in this case the candle) being altogether different.

If in "Onward's" case there were an image of the aperture at all, it must have been due to reflection from the front surface of the front lens alone, which, as regards the diaphragm, would act as a concave mirror; but, to form an image, the diaphragm itself must have been capable of readily radiating light—a clearly improper condition for the diaphragm to be in, as it should be of a dead black. But we are of opinion that, as a rule, this is not the cause of the annoyance We account for it by supposing it to arise from the shade in front, with which portrait lenses are usually furnished, and which are generally far too small in diameter, thereby cutting off a portion of the light falling on the lens obliquely in every direction, and thus a shadow of the diaphragm itself becomes projected on the focussing screen, and consequently the indistinct outline of the aperture therein is sufficiently traceable. Such a shade as we have indicated is worse than none at all, and may be with advantage removed altogether; and for the purpose of taking landscapes with portrait combinations, with a central stop, we are by no means sure that it would not be a good plan generally to renounce the front shade entirely. The only precaution to observe would be to be quite certain that the interior of the tube is properly coated with a dead black substance of an appropriate kind.

ON THE OPTICAL CENTRE.

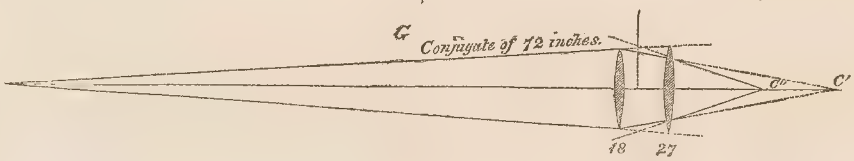
By Thomas Grubb, M.R.I.A.

No. III.

The several cases of "open compounds," exhibited by the diagrams marked A to F in my last communication, and published in your Journal of 15th February, were selected from a number of others as being at once instructive and varied. I shall now add a case which represents pretty closely one of our standard whole-plate portrait combinations, which, on examination, proved to be nearly as follows:—

Focus of first combination, 18 inches; focus of second combination, 27 inches; distance between these, 5 inches.

Neglecting the short distance between the two lenses forming the back combination, we have the representative of the whole combination (sufficient for illustration) in the following diagram G.



This diagram, it will be seen, represents the combination as applied to form conjugate foci; but let us first assume that the combination is applied to parallel rays, as in case B (February 15). We find from the formula there given the equivalent focus of G for parallel rays in either position of the compound to be 12·15—or say, P = 12·15 inches.

I have purposely avoided adopting the general symbol "F" for the equivalent focus, because our ideas of focal length are usually associated with something fixed or definite, and it is common to speak of the focus of a portrait combination as measured from some part of the construction. There is no objection to the use of the word focus, or its representative F, for the focus *for parallel rays*, which we not only know to be a fixed quantity for any compound, but which, also, we have shown to remain the same for such rays in the reversed position of the compound. "P" is to be understood to represent, throughout, *the power of a combination*, or the equivalent focal power which the compound under examination exerts *under the precise circumstances* "*pro tem.*" P therefore will be, in the case of parallel rays, equal to F (but not in any other) for the open compound.

Having found the value of P for parallel rays for the compound represented by the diagram G, it is required to find the distance of the image from last lens. Retaining the notation given in the last paper, then,

- l, l', &c., 1st, 2nd, &c. lenses of a combination.
- d, d' their intervals.
- c First conjugate or distance of object from first lens.
- c' Second conjugate or distance behind first lens, where the image of c would be formed if second lens were removed.
- c'' Third conjugate, or the component of both lenses l and l', measured from last surface.

This formula will do for any number of lenses and distances, the last or final conjugate being C''.

Now, when the incident rays are parallel, c' is equal to the principal focus of the first lens (or f), and

$$\frac{1}{c''} = \left(\frac{1}{f-d}\right) + \frac{1}{f'}$$
$$\left(\frac{1}{18-5}\right) + \frac{1}{27}$$
$$= \frac{1}{13} + \frac{1}{27}$$
$$= \frac{1}{8.775}$$

Or, if we reverse the compound, l and l' change places, and

$$\frac{1}{c''} = \left(\frac{1}{f'-d}\right) + \frac{1}{f}$$
$$= \left(\frac{1}{27-5}\right) + \frac{1}{18}$$
$$= \frac{1}{22} + \frac{1}{18}$$
$$= \frac{1}{9\cdot 9}$$

We thus see that, although the power or P is the same *for parallel rays* in reversed positions of the compound, *the distance of the image from last surface here varies.*

The diagram G, however, represents the combination as applied to form *conjugate foci*, the distance of the object being 72 inches from first lens, and the formula will be—

$$\frac{1}{c'} = \left(\frac{1}{f} - \frac{1}{c}\right) \text{ and } \frac{1}{c''} = \frac{1}{f'} + \left(\frac{1}{c'-d}\right)$$

So that, for the direct position of the compound—

$$\frac{1}{c'} = \left(\frac{1}{18} - \frac{1}{72}\right)$$
$$= \frac{1}{24}$$

and

$$\frac{1}{c''} = \frac{1}{27} + \left(\frac{1}{24-5}\right)$$
$$= \frac{1}{27} + \frac{1}{19}$$
$$= \frac{1}{11.15}$$

That is, for an object placed at 72 inches from the first lens of the combination, the image will be formed at 11·15 inches behind the last lens.

We are now in a position to find the equivalent power or P for these conjugate foci of our combination in a manner which depends for its correctness on the proposition that *the power of either a lens or a combination of such, no matter how complex, is duly expressed by the final vergencies of the pencils.*

The data previously ascertained enables us to calculate these vergencies as follows:—

For the compound represented in fig. G—

$$V = \frac{1}{c} \quad \text{and} \quad V' = \frac{1}{c''} \times \left(\frac{c'-d}{c'}\right)$$

so that

$$V = \frac{1}{72} \quad \text{and} \quad \begin{cases} V' = \dfrac{1}{11\cdot 15} \times \left(\dfrac{24-25}{24}\right) \\ \quad = \left(\dfrac{1}{11\cdot 15} \times \dfrac{19}{24}\right) \\ \quad = \dfrac{1}{14\cdot 1} \end{cases}$$

The vergencies are therefore as 1 to 5 (very nearly), and the images are inversely as these, or as 5 to 1.

Having thus obtained the proportions of the conjugates, their actual lengths are found by taking the entire distance, say 72 + 5 + 11·15 = 88 15 inches, and dividing this into two parts in the proportion of 5 to 1, thus we obtain—

Distance from first conjugate to conjugate centre, 73·46 inches.
Ditto second, ditto ditto 14·69 ,,

And, for the value of P, or the equivalent power—

$$\frac{1}{P} = \left(\frac{1}{73.46} + \frac{1}{14.69}\right)$$

Or P is equal to 12·24 inches.

We have now obtained not only the equivalent power of the combination G, but also *that point in the axis which is the more immediate object of our research, viz., the centre of the conjugates*; that is to say, for the combination under the precise circumstances in which it has been considered.

I shall now give two other methods of finding such a centre. One is a mixed method, or partly by calculation and partly by diagram, and is as follows:—

First, calculate by the formula already given the place of the second conjugate c', and of the final conjugate c'' for any given (first) conjugate c.

Next, draw the outer rays of the pencils in accordance with this data, as shown in diagram G, either of full size or to a convenient scale.

Thirdly, produce the lines showing the outer vergencies, until these lines intersect, and let fall a perpendicular from the point of intersection to the line representing the axis of the compound. The point where this perpendicular touches the axial line is the centre sought. This is shown by the dotted lines in diagram G; and if a similar process be adopted with the previous diagrams, A to E, we shall find them as in the following table :—

Diagram.	Foci of Lenses.	Distance Between.	How placed or circumstanced.	Conjugates formed.	Equiv. Power or P.	Place of conjugate centre. From First lens. From Last lens.
A	24 & 24	12	Rays parallel between lenses	24 and 24	12	6 and 6
B	24 & 21	,,	Incident rays parallel	Par. and 16	16	4 and 8
C	12 & 24	,,	Ditto ditto	Par. and 12	12	12 and 0
D	24 & 12	,,	Ditto ditto	Par. and 12	12	6 and 6
E	12 & 24	,,	First conjugate 12 inches	12 and 24	8	4 and 8
F	24 & 12	,,	Ditto ditto	21 and 21	10½	9 and 3
G	18 & 27	5	First conjugate 72 inches	73·46—14·69	12–24	1·46 and 3·54

This table, if assisted by a reference to the diagrams, needs no explanation. It will be observed that the four cases, C to F, are all the *same compound*, but exhibited under different applications.

The third method of finding a centre of conjugates is altogether practical, and may be conducted thus:—

Provide three planed boards, say eighteen inches long, nine wide, and one thick, also a couple of bridges or forked pieces of wood to support the compound for examination steadily on the upper board, so that its axis shall be directly over a centre line drawn on the length of the upper board. Fix to the centre of the lower board a projecting pin, so that the two upper boards can be turned steadily round on that centre; and mark the place of this centre on all the boards by traverse lines on the faces and edges of the boards. The lens is to be placed as directed on the upper board, and as nearly as can be judged with the conjugate centre over the pin or centre of revolution. A suitable object (a lamp or candle by night, for example) being now placed at that distance from the compound for which the conjugate is required, and either a ground glass or a cardboard surface being placed on an independent support (that is, unconnected with the support of the lens) to receive the image, then the lens with the two upper boards is to be turned round while the image on the screen is watched. Should this image remain unmoved by the revolving of the compound, then the centre of the conjugates is found, and may be marked on the compound from the cross line on the upper board, supposing this to coincide with the centre of revolution; but should the image shift to right and left as the compound is turned with the upper supporting boards, then shift the upper board with the lens longitudinally, thus bringing another part of the compound over the centre pin, and try again. After a few trials, for each one of which the distances of the object require adjustment, a position for the compound will be found for which no sensible alteration of the place of the image takes place on revolving the compound through an arc as large as its own aperture permits. The position of the conjugate centre will now be had by reference to the line on the middle board. It may be seen that the experiment can be conducted by two boards only, shifting the compound with the supporting bridge pieces.

The centre of conjugates thus found will agree with the same obtained by the theoretical or mixed process, and satisfactory proof of the change which the place of these centres undergoes will be had by trying the experiment for both a considerable and inconsiderable distance, say for distances varying between ten to three times the focus of the compound.

We are now in a position to judge of the nature of these centres. They are, in my estimation, nothing more than those places where, according to circumstances, the power exerted on one side meets the power exerted on the other—*a neutral point in fact*, and one which, practically, can be extended into a line of indefinite length wherever (as in diagram A or E) the rays pass parallel within the compound; a point in this line being however necessarily taken for the conjugate centre which divides this line proportionally with the outer conjugates. We therefore have here no *a priori* evidence that the place (or places) of these centres is better than another for placing a limiting diaphragm, while other considerations show that a different place may be decidedly preferable. A knowledge of the centres, which have been the subject of the present investigation, is, however, of considerable value in theoretic considerations, and it affords the means of finding the representative of any compound (however complex) in the shape of a single lens of definite aperture and power—a matter of no slight value in strict comparison. In my next communication on this subject I hope to examine the Petzval or orthoscopic, and also the symmetric (so called) compounds, with reference to these centres.

PHOTOGRAPHIC COMMENTS.

By T. F. Hardwich.

No. 1.

It has often occured to me, that if one accustomed to read the photographic journals from the very commencement were, from time to time, to make short notes of anything which struck him as being worthy of comment, it would be of service: amateurs just beginning the art would derive advantage from such discussions; whilst the advanced student might perhaps be encouraged to communicate his own experience, and so to add to the general stock of knowledge.

In the last number of this Journal, under the head of a Report of the Proceedings of the North London Photographic Association, I see a letter written by Mr. Oakeshot, of Ryde, referring to an analysis made by the French chemists, who assert that a quart of hyposulphite solution, of a strength of ten per cent., will fix in a satisfactory manner not more than a sheet and a half of washed sensitive paper, and that the above solution will be in a state of super-saturation with silver salt, if more than forty grains of chloride of silver be added to it. Now all this is so directly opposed to the everyday experience of photographers that it must evidently be wrong.

When Herschell first published his memoir on the hyposulphites, he described two compounds of hyposulphite of silver with hyposulphite of soda—the one containing one atom of the former salt to two atoms of the latter, and the other containing a single atom of each. If you dissolve in a solution of hyposulphite of soda rather more than one-third of its weight of chloride of silver the former of these compounds is obtained, which is very soluble in water, and has an intensely sweet taste; but if afterwards a fresh portion of chloride of silver be added to the same solution, until the weight of chloride reaches to more than one-half of that of the original hyposulphite, then the second compound is produced, which is far less soluble than the last, and not so sweet to the taste. Thus, a quart of hypo solution of ten per cent., containing four ounces of hyposulphite, ought to dissolve an ounce and a half of chloride of silver to make the sweet salt, and more than two ounces of the sparingly soluble salt.

To bring the above calculations to the test of actual experience, I took commercial hyposulphite of soda and analysed it by means of iodine, to ascertain the per centage of real hyposulphite present. A solution of ten per cent. was next made, and in two similar portions of this fixing liquid, containing each fifty grains of hyposulphite, twenty grains and thirty grains of nitrate of silver were respectively dissolved, the solutions being put away in separate bottles, in a dark place. The experiment was made on Saturday, and on Monday morning both solutions were found perfectly clear; but at the bottom of the bottle containing the hyposulphite solution most highly charged with silver a brilliant crystal had formed, perfectly transparent, and with clean cut faces, like a diamond of the purest water. Any one may repeat this experiment, but it will be necessary to take one precaution — the nitrate of silver must be converted into chloride by the addition of common salt, otherwise it will be impossible, even with the most careful stirring, to prevent some decomposition. It is therefore certain that commercial hyposulphite of soda ought to take up at least a third of its weight of chloride of silver, and to produce with it a liquid not prone to immediate decomposition, although, as I showed some time back in a paper read at the Photographic Society, any solution of hyposulphite of silver in hyposulphite of soda will tend eventually to throw down the black sulphide, and to form products analogous to the polythionic or sulphuretting series.

The photographer need not, I think, concern himself practically with this question, since he will never be able to push the action of the hypo fixing bath to the degree of saturation above mentioned. It must be borne in mind that the compound which he has to remove from the paper is not pure chloride of silver, but a compound of chloride of silver either with albuminate of silver, or with that substance which I term gelatino-nitrate of silver, which is not affected by washing with cold water. A much stronger fixing solution is required to remove these bodies than theory would indicate for simple chloride of silver, and hence, unless crystals of hypo are occasionally dropped in there will be yellow measly spots in the substance of the print visible on looking through it, although the fixing bath may be capable of readily dissolving freshly precipitated chloride of silver in the curdy state, and of retaining it in solution without any precipitation of sulphide. I do not think that MM. Davanne and Girard would be able to defend their own statements if called upon to do so; and it appears to me that, as regards the practical working of the fixing bath, a

short letter of Mr. Maxwell Lyte's is more worthy of attention, in which he shows that the same solution which had previously been working in a satisfactory manner, failed to remove the silver salt as the weather changed and the thermometer fell several degrees.

Leaving the subject of fixing baths, I pass on to notice a communication from Mr. Forster, on the use of gum-arabic as a preservative agent, which communication I hope he will follow up in due time with a second, giving his experience with the same substance during the present summer. One question I will ask:—Why does Mr. Forster wash his plates with a *limited* quantity of water? If he were to get rid of the whole of the nitrate of silver by washing first abundantly with water, and then with salt and water, and lastly with water again, he would find his plates quite as sensitive as Fothergill plates, according to my experience—that is to say, if in addition, the thick solution of gum were left to dry upon the surface of the film. I know the appearance of the brain markings of which he speaks very well, but have not met with them now for more than fifteen months; and I think I can promise Mr. Forster that, if he will prepare pyroxyline by the formula with weak acids, given in my paper in the last Journal—wash away the whole of the nitrate of silver—and develop the plates by pouring the solution backwards and forwards from a measure, he will no longer be troubled with this annoyance. Citric acid in the developer, however, appears too powerful a retarding agent for gum plates used without free nitrate of silver; it diminishes their sensitiveness and produces metallic images.* Glacial acetic acid, fifteen to twenty minims to the ounce, gives a picture with more of a red tone, and does not interfere with the bringing out of the dark parts. On an albumen plate I have not found the citric acid to affect the colour of the image, and I can understand that it might not do so to the same extent when gum and nitrate of silver were left together upon the film. In the case of gum without nitrate, the tendency to form an image of a red, brown, or amber yellow colour is not so decided, and therefore it is of more importance to balance the amount of acid correctly.

P. S.—Since writing the above, I have taken the trouble to pick out the little crystal before alluded to, and examine it. It is transparent and permanent in the air, very dense and highly refracting, hard and gritty when crushed with a glass rod, has a sweet taste, and is soluble with difficulty both in cold and hot water. The aqueous solution throws down a thick white deposit with nitrate of silver, which almost immediately becomes yellow and then black. After the addition of nitric acid, chloride of sodium precipitates chloride of silver from the aqueous solution. These tests prove the crystal to have been a double hyposulphite of soda and silver, and, from its sparing solubility, probably the second of Herschell's compounds, viz., that represented by the formula—$A_g\,O,\ S_2\,O_2\ +\ Na\ O,\ S_2\,S_2.$ Lenz describes this body as a dirty white powder, and I am not aware that it has hitherto been obtained in crystals so well defined.

P. S. No. 2.—At the expiration of a week from the time of making the experiment both solutions of hyposulphite remain clear and colourless, but the bottom of the bottle containing the larger quantity of hyposulphite of silver is covered with sparkling crystals.

* This observation applies to pictures taken in a bad light, and with collodion newly iodised. In a bright light, and with older collodion, I should expect to obtain sufficient intensity even with citric acid, which always possesses the merit of preventing fogging from irregular reduction of silver.

ON PRINTING PHOTOGRAPHIC PICTURES FROM SEVERAL NEGATIVES.

By Henry P. Robinson.

[Read at a Meeting of the Photographic Society of Scotland, March 13th, 1860.]

Rather more than two thousand years ago Zeuxis, of Heraclea, painted his famous picture of Helena for the people of Crotona, in the composition of which he selected, from five of the most beautiful girls the town could produce, whatever he observed nature had formed most perfect in each, and united them all in one single figure. A reference to the dim traditions of antiquity might perhaps be considered out of date in treating of an art which was discovered only a few years since; but the purpose of the paper I am about to read this evening is to induce you to do in photography something similar to that which the old Greek did in painting, that is, to take the best and most beautiful parts you can obtain suitable for your picture, and join them together into one perfect whole.

I have frequently been requested to give some information on the method I employ in producing photographic prints from two or more negatives: the plan is so simple that I have never before thought it worthy of a written description; however, I have now prepared a few prints, the inspection of which will enable you to understand how these pictures are produced.

It has often been remarked that an artist who would attempt this kind of work must have very great advantages over other photographers—that he must have time to hunt after the scenes of his pictures, since it is a matter of chance in finding bits of landscape scenery to suit his figures; also, that few people would take the trouble to carry their models and accessories into the country for the sake of one or two pictures, and the possibility of securing none, as models are sometimes refractory and difficult to arrange. But the truth is, that a great variety of appropriate scenes for figure subjects might be formed on a small piece of ground: the principal parts of most of my photographs containing figures and landscapes combined, were taken in a small back yard, about fifty feet long by twenty feet wide. In this I have thrown up a bank, and partly covered it with wild flowers and ferns; the other part consists of an imitation of a mountain spring, covered with honeysuckle, brambles, &c. With this arrangement I can get a foreground for almost any variety of landscape: a heath scene, or the top of a mountain, as in *Nearing Home;* or the side of a river, as in *Here they come!* and *Preparing to cross the Brook;* or part of a wheat-field, as in *Lavinia.* At the foot of the bank is a hole, caused by the removal of the earth to make the bank; into this runs the waste water from a print-washing apparatus which forms a river. In this confined space, with the assistance of a spade and a little ingenuity, a great variety of effects might be produced.

Perhaps the best method of describing double printing will be to take a very simple subject first—although it cannot strictly be called a double print, as only one negative was used. In the picture I have named, *Here they come!* and for which your society has honoured me with the silver medal, the two figures were placed in position on the bank I have described, and a negative taken of them. At the top of the bank was a brick wall: this was objectionable, and had to be removed from the picture; to do which a print was taken of the plate, but neither toned nor fixed, the figures and bank carefully cut out, and the remaining portion of the paper neatly pasted on the negative. Another print was then taken, in which the sky appeared too white; therefore the print was laid on a board, the figures and bank covered exactly with the impression from which the sky had been cut, a clean glass placed over the whole, and the board was carried into the light and the sky graduated down. This proceeding is very simple, and I have no doubt is known to you all, but it will better enable me to describe that which is to follow.

The next step is to add a landscape to a figure, of which *Lavinia* and *Nearing Home* are examples. The same bank has been employed for the figures in these pictures as in *Here They Come!* but instead of a graduated sky a landscape has been introduced: this is accomplished by taking a landscape negative to suit the subject (which should not be of too important a view so as to overpower the figures, but should rather serve to throw them out in relief), and, cutting out so much of the figure and foreground as will come before the distant view, paste it on the landscape negative: when the negative is printed, it will leave the place for the figures and foreground, plain paper: if the figure negative is now covered over so as to print only in the places which are left for it, the picture will be complete.

At first sight it will appear difficult to place the partly printed pictures in the proper place on the corresponding negative. There are many ways of doing this, and either of which might be chosen to suit the subject: sometimes a needle might be run through some part of the print—for instance, in the angles formed by the joining of the bank to the figure,—and the point being allowed to rest on the corresponding part of the second negative, the print will then fall in its place at that point: some other point has then to be found at a distance from the first; this might be done by turning up the paper to any known mark on the negative, and allowing it to fall on it: if two points separate from each other are on the right place, all the others must be correct. The printing-frame can then be closed, and placed in the light to print. This operation is easily performed after a little practice; in fact, all my composition pictures are printed by boys.

Another way of joining the negatives is by placing a candle or lamp under the glass of the printing-frame, and throwing a light through the negative and prepared paper; the joining can then be seen and easily adjusted.

These methods can be applied to any number of negatives forming one picture. I exhibit a print of *Fading Away,* which was printed from five negatives; the joinings are purposely widened to

show how they are combined; you will observe that the composition was so arranged that the divisions occupy unimportant places, easily hidden. This was the first picture I ever composed in photography: of course there are many faults in it, which would not appear so conspicuously if I attempted the subject again. I am sorry to say that the negatives, after giving about two hundred impressions, were injured by damp, through the carelessness of an assistant.

It is sometimes necessary to print a single figure from two negatives: *Ophelia* is an example of this kind. The head was taken from one model, and the figure from another; the print exhibited will show how this is managed: you will here notice that the edges of the two negatives are shaded off, and allowed to fall over each other.

The mechanical difficulties in this kind of work are nothing—amateurs of small experience might conquer them with a little practice: the great difficulty is the choice of a subject, the selection of models, and the drilling of them into their work. The principal figure in *Fading Away* had three years' practice in expression for photography before a satisfactory picture was taken.

It is rather singular that so little has been done in this branch of photography. The method has been practised for many years by the gentleman who first brought it into successful practice, Mr. Rejlander. His pictures have been prominently before the public for some years; but I do not know of anyone, except myself, who has attempted to imitate him. It cannot be that we have no artists among us; we cannot all be so devoted to science that we discard art; our exhibitions give good evidence that there are men practising our profession who can group figures together. It is possible that prints from several negatives combined do not pay so well commercially as proofs from a single glass; but that should not prevent enthusiastic followers of such a pleasing art from pushing it to its greatest extent; and its application to the highest art purposes is certain. But art is thoughtful work for earnest men, and until a photographer devotes his time entirely to a few good pictures each year, we shall never know what artistic effects can be produced. There are other causes which tend to stay the progress of art in photography. Some critics, even in journals which we might expect to encourage any efforts to advance art, have endeavoured to put down the attempts (failures they might be, but they are well meant) of the few who try to get out of the beaten track—the old *Portrait of a Gentleman*, or *Landscape* "*without*" *Figures*, so continually recurring in our exhibitions; they are not content with the condemnation of individual efforts, which would be only fair criticism, but their disapprobation extends to the whole system; one even goes so far as to express not only his *indifference*, but his *dislike* to all attempts to make figure-pieces. It is not the fault of photography that the man has not yet appeared who will make the best use of the abundant materials provided for him.

It has been said that the possession of a good model is a lucky accident; but that is far from being the case. Art can be extracted out of almost anything. A Hunt, inspired by a Ruskin, can make a picture from an oyster-shell. Take any model, find a suitable subject for it, (and here is an occasion to exhibit the *art* that has been denied to phography; for a subject must be imagined, and imagination is art,) and instruct it well in its position and expression. Do not be discouraged by one failure or a dozen; fix in your mind the idea you mean to express, and persevere until it is represented. It will be found that the less models know of photography the better. Actors are always bad models; they know so much, and allow the operator to know so little, that the result is not an artistic picture, but a theatrical study. I am not before you to-night to preach the crusade of art in photography; I have long expected abler men to do that. Every meeting produces speakers on lenses, and cameras, and processes, but very little is said about the application of these necessary instruments and discoveries. I think we are now as perfect as possible in manipulation, as far as black and white are concerned. We want to apply these discoveries to higher purposes than we have hitherto done. The means of producing pictures in our art are as good as those of producing paintings in Raphael's time; and nothing but a deep and earnest study is required to make our pictures rank with the works of the most famous men.

ON GLASS TRANSPARENCIES.

By J. P. M'Adam.

[Read at the last Meeting of the Caledonian Photographic Club.]

The subject I now intend bringing before you has not, I am sorry to say, received from the public its due amount of appreciation; and this, I fear, is chiefly owing to the fact that photographers are not sufficiently alive to their interests, to cultivate this branch of their art with the necessary enterprise. That the public would appreciate such works were they properly brought before their notice is, I think, evident from the fact of the enormous prices sought and obtained for the only class of transparencies that has been published: I allude to glass transparencies for the stereoscope. Who that has looked upon a *chef d'œuvre* of this class by Ferrier but must feel almost sad to leave it, even in favour of a similar subject, on paper, in the finest style. I submit to your inspection two stereoscopic views from the same negative, one on albumenised glass and the other on paper: each is perfect in its own way, but how superior is the glass to the paper! Photographic transparencies have hitherto been chiefly confined to such small objects as shades for lamps, and slides for the phantasmagoria lantern and stereoscope. I, at least, have never seen any work of magnitude executed in this style. When I say this, I ought, perhaps, to except this one which I now submit to your notice, which was executed by myself a few days since. The size in itself is such as entitles it to respect, being not less than thirty-six inches by thirty. The subject is a *View of Leith and the Frith of Forth*, taken from the narrow gap between Salisbury Crags and Arthur's Seat, with the green valley (now, alas! fallen a victim to the burrowing propensities of some of our rifle volunteers) in the foreground. It is magnified from this twelve by ten negative, and seems to have suffered nothing in point of sharpness and delicacy of gradation by the enlarging. The negative was taken intensely sharp, to ensure which the day selected was one on which there was not a breath of wind stirring: the camera and camera-stand were exceedingly strong and rigid, and the lens (a thoroughly corrected meniscus) used with a very small stop; the plate was a "Hill Norris" one.

The camera I use for enlarging is a large deal box, with a travelling partition inside, in which the lens is fixed. In the front end of the box is an arrangement for holding the negative to be enlarged, and at the back end (which is constructed so as to expand or contract like an ordinary expanding camera) is placed the sensitive plate. The focussing is effected by a brass wire, with a knob, which projects at the back, by which the partition holding the lens is made to traverse longitudinally.

Everything being ready, the camera is pointed either to the sky or to a white sheet on which the light is received. For operating in the daytime I employ the camera I have now described; but for my illustrations of to-night, I intend making use of a phantasmagoria lantern, which I will illuminate with this case of small Bunsen batteries. For night purposes the electric light pleases me much better than the lime or any other kind of light that I have yet tried; the purity and intensity being such as to allow a small stop being used. The lantern is of the ordinary construction: the object-glasses are achromatic, and the condensers of the double kind, with which all good lanterns are fitted; they are six inches in diameter. The view I intend enlarging is very small, being one originally of a pair for the stereoscope. The plate I have prepared on which to take the magnified image is twelve inches by ten, not so large as I usually do, but large enough to show you the *modus operandi*. It was prepared last night with a dilute solution of honey, and if I time the exposure aright I am quite certain of a good picture.

[Mr. M'Adam proceeded to light the lantern, the brilliancy of the light being such as to call forth bursts of applause, and after inserting the negative, and adjusting the focus on a sheet of white paper, stretched on a frame, he dexterously substituted for it the prepared plate, which was impressed, developed, and fixed, in a wonderfully short space of time; and, after having been washed, dried, and varnished, was handed round the room for inspection. The details and tone were very fine, and the picture (a view of *Edinburgh Castle* from the Greyfriar's Churchyard), was unanimously pronounced to be perfect, even to the rendering of the light fleecy clouds which floated in the sky.]

Mr. M'Adam then resumed his paper.

As a specimen of transparencies for the lantern, I will, before the lantern is removed, exhibit this view of the *Falls of the Clyde*, taken when few tourists are abroad, and when cameras and lenses are on the shelf for a season. The negative was taken early in last January; and I would here remark that, to see the falls of Clyde aright, you must see them when the water, arrested by the intense frost of winter, hangs solidified over the face of the cliffs, sparkling like a thousand diamonds, and refracting the solar beams in the most intense and gorgeous hues.

I hope the day is not far distant when the windows of our churches and other public buildings, instead of being disfigured as

they now are by bareheaded and barefooted saints, with garments of "sky blue and orange yellow," which set at defiance all the laws of good taste by their gaudy patchwork of colours, will be ornamented with transcripts of nature, and, if portraits are to be introduced, with faithful representations of those who by their intellects and virtues have rendered service to the cause of religion, science, or literature.

I intended to have gone rather further into the manipulatory details than I have done, but as there is nothing essentially new in the process by which these pictures are taken, I have deemed it better not to do so, but will with pleasure answer any question proposed to me.

[Mr. Brown: I am quite delighted at Mr. M'Adam's lucid experiments, and would feel obliged by his informing us what developer he uses?

Mr. M'Adam: I use the gallo-citrate of iron, made by mixing together solutions of pyrogallic acid and proto-sulphate of iron, and adding solution of citric acid, till the precipitate be barely dissolved.

Mr. Montaigne: What kind of collodion do you use, and how do you manage to excite such a large plate as this thirty-six-inch one?

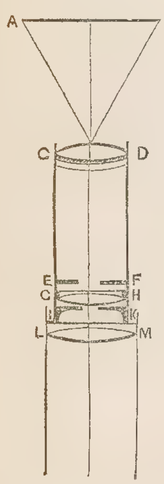
Mr. M'Adam: The collodion is iodised with equal parts of the iodides of potassium, ammonium, and cadmium, with a minute portion of bromide of ammonium. The exciting bath is a large, flat, home-made gutta percha one, with a reservoir at one end sufficient to hold the nitrate of silver, which, when the coated plate is laid in the bottom of the bath, is by means of a slight tilting made to flow over the plate at one sweep.

The meeting then assumed a purely conversational character, and was afterwards adjourned.]

OBSERVATIONS ON A METHOD OF ENLARGING AND MULTIPLYING NEGATIVES.

By William Griffiths.

[Read at a meeting of the Chorlton Photographic Association, 14th March, 1860.]



A B Negative, 3 inches in diameter.
C D Back lens of ¼ plate double combination.
E F Stop, ¾ inch in diameter.
G H Front lens of ¼ plate double combination.
I K Stop, ⅜ inch diameter in contact with lens.
L M Landscape lens, 2¼ inches diameter.

Before proceeding to make a few observations on the method of enlarging and multiplying negatives, brought before your notice at a former meeting, I may be allowed to express my regret and disappointment at not being able to produce for your inspection this evening such specimens of the process as I could have wished.

You will all, no doubt, understand why such is the case when I explain to you that the negatives for enlarging ought to be very faint but full of half tone, semi-transparent even in the high lights, and have little intensity; such negatives, in fact, as result from a slight over-exposure and early checking of the development.

Now I must confess that I do not happen to have in my collection more than two or three that are at all suitable, and they have been almost spoiled in my attempts to bring up the intensity sufficiently for printing from in the ordinary way.

I find also, on looking over the collections of some of my friends, that they, like me, have not been in the habit of keeping by them negatives that are too weak and transparent to print from.

The only ones that are well adapted in all respects (if I may judge from the beautiful transparencies printed from them) are some in the possession of our friend Mr. Wardley, and who, it may be recollected, kindly volunteered to lend me two or three as soon as he could find an opportunity for printing them. Unfortunately from press of business and ill health he has been unable as yet to do so. However, I trust that by another meeting I shall not have occasion longer to trespass on your indulgence.

Before venturing to make any remarks upon the advantages and the convenience of a good and simple method of enlarging negatives, it may perhaps be desirable for the satisfaction of those members who were not present when I first brought this subject before your notice, if I should give a brief description of the method I find to give the best results. And, first, as to the size and quality of the original negative to be enlarged:—I find that the best diameter to enlarge from is one of from two-and-a-half to three inches; for, if you much exceed this, the angular field of your ordinary photographic lenses, which I shall presently recommend you to use as magnifiers, is insufficient to take in the whole of it. I need not tell you that it is essential it should be perfectly sharp and distinct all over, and free from fog and stains. As to its quality, you will have gathered what that should be from my previous remarks. The camera and lens I employ for taking my original negatives, as you will see, is a very diminutive affair, but quite large enough for all practicable purposes. The lens is a double combination one, of a combined focus of about two-and-a-quarter inches from the back lens, giving a sharp picture two-and-a-half inches in diameter.

The varnishing of the negative is not only unnecessary but sometimes detrimental.

The lenses I prefer to use for enlarging are three in number, namely, the quarter plate double combination, together with an ordinary single or landscape lens, of from twelve to fifteen inches focus. The front lens of a half-plate double combination will, if of the requisite focus, answer perfectly well in lieu of a landscape lens. The mode of arranging them, as well as the positions and diameters of the stops made use of, will be much better understood on reference to the rough sketch now before you than by any verbal description I can give.

No extra apparatus of any kind, beyond what most photographers are already possessed of, is required—namely, two cameras, one a quarter-plate with its double combination lenses, and either a half or full plate one, with the single landscape lens. All that you have to do is to screw the two cameras on to a flat board, front to front, taking care that the smaller one is sufficiently packed or raised so that the axial line of its lenses shall correspond exactly with that of the single lens of the larger camera.

I do not make use of any condensing apparatus or reflectors for increasing the amount of light transmitted through the negative; not that I think them useless under some circumstances, particularly when the light is deficient, but because I have been loath to complicate the process by their use, seeing that the advantage gained is only a slightly diminished exposure. The negative to be copied is placed in the dark slide of the quarter-plate camera, collodion side inwards, and securely fastened, so that when the door is opened it may not fall out. Care must be taken, by means of a piece of cardboard of the size of the slide, and with a hole cut out a little less than the negative, to prevent any light passing into the camera, except what passes through the negative.

The board with the cameras is so arranged that the unobstructed light of the sky shall pass through the negative in the smaller camera.

If the direct light of the sun is made use of, it will be necessary to place a piece of finely-ground glass at a little distance before the negative, which will have the effect of more equally illuminating it.

The distance of the negative from the lenses will have to be varied according to the amount of enlargement required, which is easily done by drawing in or out the sliding parts of the camera. I first take a transparent positive, with wet collodion, of the same size as the negative; I then replace this latter in the slide by the positive, and proceed to take my enlarged negatives from it.

I should never attempt an enlargement beyond four or five diameters, and that only from negatives that are tolerably sharp all over. The exposure required will, of course, vary with the light and density of the transparent positive (which must be very faint): from one to six minutes will be about the minimum and maximum for five diameters.

It must be understood that the arrangement of lenses here recommended is only suited to the enlargement of small negatives or positives; therefore if it be desired to enlarge from an original negative, which is, say four or five inches diameter, it will be necessary to replace the quarter-plate double combination by one of half-plate, or, as our worthy treasurer, Mr. Hooper, suggests, place the landscape lens before and in immediate contact with the back lens of the quarter-plate double combination, but with the convex side to the negative to be copied.

I will now, with your permission, say a few words upon the advantages that may be expected from a good and simple method of enlarging.

In the first place, we should be enabled to dispense with large and cumbrous apparatus in our journeyings after the beautiful in nature and art; the personal labour involved in its transit from place to place being, as you will all admit, anything but agreeable, leaving out of the question how materially it detracts from the pleasure we should otherwise enjoy. And in the next place we can, with a

small and short focussed lens, obtain views of subjects that cannot, from their position, be taken at all by one of long focus. And again, as a rule, it will be found that small short focussed lenses take in a much greater angle of view than long ones, besides giving greater depth of focus, and these, added to the diminished exposure required, are advantages which every practical photographer will at once be able to appreciate.

I may also observe how much more free from distortion and true in perspective are pictures obtained in this manner than those taken with long focussed lenses.

I need scarcely remind you with how much greater facility small plates can be prepared than large ones, by any of the dry processes, and of the greater chances of their turning out successful.

In conclusion, I will say a word or two on enlarging processes generally. I am of opinion that they have hitherto proved unsatisfactory, principally from our having experimented with ordinary printing negatives, and also because we have attempted too great an enlargement of what has been, probably, but a very unsuitable negative for the purpose.

If we carefully compare a negative of say three inches diameter, taken with a small lens, with one of twelve inches, taken by a large one, of the same subject, we shall find that the former has a decided advantage over the latter in sharpness and in being a far more truthful representation of the object. Now, I maintain that it is perfectly practicable to enlarge the smaller one to the same size as the larger, and that it shall then be equally sharp with the original large one, and without any of its perspective defects.

I will not say, however, that if you enlarge it to fifteen or twenty inches that it will then be equally sharp with the one of twelve inches taken direct, for that would be quite impossible.

An opinion prevails that it is not practicable to enlarge a picture even to a small extent without considerable loss of half-tone. This is true when applied to negatives originally taken for printing from, as I have previously shown; but it is not so when suitable ones are employed, for in that case whatever is found in the original will be faithfully reproduced.

I am afraid I have occupied more of your time than perhaps some of you may think such a stereotyped subject warranted, particularly as I have advanced nothing that was not previously known to many of you, but I have done so from a strong conviction of its importance to photographic art.

ON THE MEASUREMENT OF THE CHEMICAL ACTION OF THE SOLAR RAYS.*

By Professor H. E. Roscoe.

It would at first sight appear superfluous to comment on the importance of the sun's action in maintaining and supporting the animal and vegetable life existing on the globe, yet it is necessary to consider the subject in order to form a just idea of the magnitude of the sun's action upon the earth. We must not, however, limit our view to the animals and plants restored by solar light and heat: we must remember that each drop of rain, each breath of wind are dependent on the same cause. By the study of geology we see, not only in coal-fields, but in the sedimentary crust deposited upon the surface of our planet, evidences of the enormous power the sun during his epochs has expended upon the earth.

The red rays of the spectrum, which vibrate most slowly, are those which mainly produce changes of temperature: they are, *par excellence*, the *heating* rays. To them is due all those motions in the atmosphere which we term winds, and those enormous phenomena of distillation and deposit we term rains; and the amount and distribution of these heating rays determine what may be called the *thermal* climate of a given place. Those solar rays which, on the other hand, vibrate most rapidly, and are situate at the violet end of the spectrum, are called the *chemical* rays, because it is by them that the chemical action produced by the sun's light is effected. It is by these rays alone that the plant is enabled to decompose the carbonic acid of the air, to assimilate the carbon for its own use, and to set free the oxygen for the subsequent use of animals. Thus the character of the flora of any place depends mainly, or to a great extent, upon the amount and distribution and variation of the chemical rays which fall on that place, and determine what may be called its *chemical* climate.

Now the measurement of the quantity of solar radiation which falls on the earth is a most important matter — a most important material for the determination of the physical history of our globe. We possess a means of measuring the effect of the heating rays or temperature in the thermometer; but up to the present time no such measurement has been adopted for the chemical rays, not so much because meteorologists have ignored the subject as on account of the difficulty which seemed to surround the attainment of an accurate measure.

If it be asked—"What do we mean by chemical action of light?" we answer, by showing its effects in blackening chloride of silver, and decomposing it; changing not only its external appearance, but also its internal physical properties. Again, if we put newly-gathered leaves into a bottle containing carbonic acid, and allow the sun's rays to fall upon them, we find that those leaves possess the power of assimilating the carbon and setting free the oxygen: we see the little bubbles of oxygen rise up through the water, and we can collect them to prove the fact.

There are two gases known as chlorine and hydrogen, which, when mixed in equal proportions, combine and form hydrochloric acid gas: they combine under a great variety of circumstances, but the one which now especially claims our attention is that they combine under the influence of light, whereas, in the dark, they do not combine at all. In diffused light the combination is gradual, but under the influence of the solar rays the combination is effected so suddenly, and the heat evolved is so great, that explosion ensues.

Now for the measurement of this action, produced not only by solar light but by other means, we want some chemical instrument, which, like the thermometer, shall show objectively the amount of chemical action—a photometer, a correct instrument—one in which the indications shall be in exact proportion to the amount of chemical rays emanating from any source, and represent that amount.

An instrument has been contrived which measures the chemical action of light by means of the mixture of chlorine and hydrogen gases, which form hydrochloric acid. It consists of three parts: one in which the hydrochloric acid gas is decomposed by an electric current. The component gases then pass into the second portion of the instrument, where they are exposed to the action of light; and from that into the third portion of the instrument, where the measurement is made. A great many precautions are necessary to be taken before the instrument is in a fit state for use. The gases have to be passed through the instrument for more than a week. To get it into working order, the apparatus is filled with gas, and placed in a dark room, with a small lamp or candle to light the operations. The instrument being fully charged with gas, the source of light, whatever it be, is brought to bear upon the insolation vessel; and the rays being allowed to fall upon the mixture of gases, immediate combination takes place: hydrochloric acid is formed, and a diminution of space ensues.

There is therefore a constant motion along the index tube; and every minute, or every two minutes, we read off the rate at which the water moves along the tube, which, being attached to a scale, enables us to measure the chemical action, because the amount of hydrochloric acid formed is proportional to the amount of light. Thus, the chemical photometer is an instrument by the help of which the quantity of hydrochloric acid thus formed can be accurately measured. It is therefore a reliable instrument.

The instrument requires to be graduated, by taking a certain amount of light, and observing its action. We take the blue flame of carbonic oxide gas, burning at a certain rate, and at a certain distance from the instrument: a definite result is obtained, and we mark that result, whatever it be. It does not signify where the instrument marks the unit of light: whether it be one foot, or ten feet, or ten divisions of the scale. We have a certain amount which can be taken as the unit or standard of light. If this flame be placed, say at a distance of one *metre* from the instrument, we obtain, in the dark room, a certain amount of chemical action, and that amount we take as *one*.

Thus we have a comparative measurement of the chemical action of light. The possession of a constant source of light is the first essential for the measurement of photo-chemical actions:—

1. A flame of pure carbonic oxide, burning in the air and issuing from an opening of a given size, at a given rate, is employed as the standard flame.
2. The unit amount of chemical action is that effected by such a flame upon the sensitive mixture of chlorine and hydrogen during one minute, at a distance of one metre.
3. The quantity of light producing this action is called one chemical unit of light, and ten thousand of such units, one chemical degree of light.
4. The chemical photometer is graduated by observing how many of these chemical units of light correspond to one division on the scale of the instrument.

(To be concluded in our next.)

* Condensed from a Lecture delivered at the Royal Institution, on the 2nd instant.

ON THE REPRODUCTION OF ENGRAVINGS, PRINTS, ORDINARY WRITING OR LETTERPRESS ON PREPARED PAPERS BY CONTACT IN THE DARK.

By C. J. Busk.

[Read at the Blackheath Photographic Society, 19th March, 1860.]

The pictures shown this evening are the result of a process I discovered about twenty years since, by which engravings, prints, letterpress, or writings with common inks, may be copied on prepared paper, by contact with it in the dark. The image, at first invisible, will be developed as a negative, by holding the paper by itself for a short time in bright sunlight: a few seconds suffice in some instances, but a longer exposure is requisite when the sun is not bright.

I am unable to fix with minute accuracy the date of this discovery, but it was in the year 1840. I was then residing at the Cape of Good Hope, and in the course of that year used occasionally to prepare papers with salt and nitrate of silver, according to the formulæ given in some of the periodicals of that time, for the purpose of copying the leaves of plants, &c. This was done over night, and the papers were then placed between the leaves of books to preserve them till the morning.

On one occasion, in order to vary the experiment and try something new, I steeped some paper in a solution of tartaric acid (about a teaspoonful to a tumbler of water) instead of the salt solution, and after being dried it was immersed in a solution of nitrate of silver, sixty grains to the ounce of water: again dried and placed as usual in a book. On exposing it next morning in a bright sunlight, instead of an image of the object placed on it to be copied, I was greatly surprised to see a totally different picture appear as if by magic.

Ultimately on reference to the book in which the paper had been during the night, I found I had a negative copy of the picture it had been in contact with.

Struck by the singularity and unexpected result to this my earliest original experiment in photography, I prepared other papers in a similar manner, and was equally successful with them. I recollect one in particular: on a half sheet of foolscap I obtained a very distinct copy of the *Warwick Vase*, from an engraving in the *Saturday Magazine* (I think it was called), a periodical of that time. The copy was very clear and well defined, and of a tolerably dark reddish slate colour. This picture was shown to many persons, and was in existence for some months; what at last became of it I do not know. It was not fixed otherwise than by simply washing in water, and it did not seem to lose its distinctness during the period I recollect it.

Only practising photography as an occasional amusement in the most simple way, it did not occur to me to take any steps to bring the matter to the knowledge of scientific persons, and in the course of a short time I ceased to make further experiments, but not until I had ascertained that oxalic, citric, and some other acids produced similar effects.

Since I have been in England, during the last ten or twelve years, this experiment has been only occasionally spoken of, and a few repetitions made with tartaric acid to show the effects. Within the last month, however, I have been urged by our President, Mr. Glaisher, and by Mr. Heisch, a member of the society, to bring this discovery to public notice, as it might probably be made available for some useful purpose.

The experiments I have made of late, though still incomplete, show very interesting and satisfactory results. I hope others may feel inclined to investigate the subject also, with a view of eventually bringing it to practical use.

From what I have done, I think it very probable that negatives can be produced that will allow good positives to be printed from them. Until lately I imagined that an organic acid was a requisite ingredient to use in preparing the papers, for my earliest trials with inorganic acids were not successful; but more careful experiments of late show that, so far as I have used them, they will answer equally well. Also I have found that paper dipped in a solution of nitrate of silver alone, after a few hours' contact with an engraving or print, will give a faint image in bright sunlight (probably in consequence of a little free acid in the nitrate of silver solution), and even if the image should not appear after a few minutes' exposure, it can be developed by pyrogallic acid, one grain to the ounce of water, with a few drops of nitrate of silver solution added; but the effect thus produced is different to that when it is developed by sunlight alone. The image which comes out appears of a different shade of colour to the rest of the paper and changes to a white metallic lustre, whilst the ground turns to a dense black.

In order to produce good effects with distinct whites, it is requisite, and is the main feature of my process, to steep the paper in an acid solution. Different acids give slight differences in the clearness of the whites. Glacial acetic acid I have found to produce the very best whites, and it also ensures uniformity of colour in the dark parts.

The twenty-six pictures, measuring six inches by eight, now before you, are the best I have been able to make within the last few days. The weather has not been very favourable for developing the image. Each picture has attached to it the formula according to which the paper was prepared. They were nine hours in contact with the engravings, letterpress, and writings to be copied —not, be it understood, that such a length of time of contact is requisite, but simply because it was most convenient to prepare the papers over night, and to let them remain on the engravings till morning. Half an hour or an hour of contact is enough, and probably much less time will do. I have got a picture after five minutes' contact, and which after contact, but before exposure to sunlight, was placed between sheets of blank white paper for a day and a half. It then came out as perfectly as those longer in contact, and exposed immediately after removal from the original.

Two of the specimens on the table, marked S. P. 111 and 112, were nine hours in contact, and then twenty hours between blank papers: no difference in distinctness of image or clearness of whites can be distinguished between them and the others. They and many of the other pictures have been taken from the engravings in the *Art Journal*, representing the articles shown at the Great Exhibition of 1851. One is from a coloured example of Minton tiles, in the September number of that year, and shows the different effects of different colours — blues producing yellows, and reds and yellows giving whites, more or less clear; others are from engravings and letterpress in different books; some are taken from manuscript writings of the year 1845, and one from a machine-pressed copy of a letter, written 6th June, 1848, as you will perceive on inspection.

It is not at all necessary to expose the engravings or writings, or other designs, to sun or daylight before placing the prepared papers in contact with them. A design that has not seen light for years can be taken equally well, and in as short a time. Some of the specimens shown are on Turner's negative paper — some on Saxe paper, both positive and negative. Some of the papers have a distinct picture on each side—some on one side only—intended for use as negatives to print from. The white back to the paper has been obtained by placing a piece of black transfer paper in contact with it. A long exposure to the sunlight has not the least deteriorating influence on this whiteness, when glacial acetic acid has been used in the nitrate of silver solution, and applied on both sides of the paper.

This change, produced in the prepared papers by their having merely been in contact with black and some other colours, and which prevents discolouration on exposure to sunlight, is exceedingly curious. Perhaps some one more experienced than myself in photographic chemistry may be able to explain the nature of the chemical action that produces this singular result.

The papers have nearly all been wetted on both sides with the two solutions used in preparing them. The proportions of the ingredients have been varied for experimental purposes; — the acidifying or first solution in which the paper is steeped has been, for some, eighty grains tartaric acid by itself in an ounce of water; for some, eighty grains tartaric acid, with one drachm glacial acetic acid added; for some, twenty grains tartaric acid, with half a drachm glacial acetic acid; and for some, fifty grains tartaric acid alone; and for others, one ounce glacial acetic acid in two ounces water, without tartaric acid.

For the sensitising, or nitrate of silver solution, I have used for some time fifty grains of nitrate of silver for some; for some, sixty grains; for some, ninety grains to the ounce of water. The nitrate has been used by itself, and also in combination with glacial acetic acid, half a drachm to one drachm to the above proportion in an ounce of water.

These various proportions give slightly different shades of colour to the negatives, and the shade of colour is also affected in some degree by the nature of the size in the paper, those sized with gelatine being rather redder than those sized with starch.

Of the various mixtures I have used, I am inclined to think the following proportions will give the best results, and should be applied to both sides of the paper:—For the first, or acid bath, eighty grains of tartaric acid by itself to an ounce of water; the paper to be immersed for a short time and then dried by a moderate heat; then immersed or well wetted in a solution of nitrate of silver of

fifty grains, or not more than sixty grains at most to the ounce of water, with about half or one drachm of glacial acetic acid added. Equally good results are obtained by twenty grains of tartaric acid and half a drachm of glacial acetic acid, for the acidifying solution; and also by one ounce of glacial acetic acid mixed with two or three ounces of water, and the above mentioned nitrate of silver solution. Nitric acid, about one drachm to the ounce of water, has also given good pictures.

The sharpness of definition and the whites in these negative pictures being so good, the only desirable point still to attain is to give greater intensity to the dark parts. With this object in view I am still experimenting, and with good hope of succeeding shortly. It will then give me pleasure to communicate the results, with particulars, to this society.

Before I conclude I may observe that, within a recent period, I have seen mention made in the *Year Book of Facts* for 1858, pages 208 and 209, of some experiments by the celebrated photographer, M. Niépce, of Paris, of a somewhat similar nature to mine. He used ordinary sensitive paper, and only succeeded in obtaining a faint image after placing it in contact with an engraving or other design, which it was indispensable should itself have been previously exposed to strong light for a considerable time.

The discovery of my process was eighteen years prior to this, and by it the exposing of the pictures or designs to be copied (to the light in the first instance) is not at all necessary, however long they may previously have been in the dark; and the image produced is almost all that can be desired in a negative. I do not think that by using ordinary sensitive paper, good negatives with clear whites can be produced, but consider the employment of acids in the preparation of the papers to be indispensable in order to obtain them.

Meetings of Societies.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

The annual meeting was held at Myddleton Hall, Islington, on the 28th ult.,—George Shadbolt, V.P., in the chair.

The minutes of the last meeting having been confirmed,

The "Report of the Committee" was submitted as follows:—

THIRD ANNUAL REPORT.

The time has again arrived that your Committee should address you, and it congratulates you on the prosperous state of the association.

The meetings have been well attended, and papers read of no ordinary character and merit. Much that is novel in photography has been fully discussed; and the mutual desire of the members to assist each other in overcoming the many difficulties of the art has caused the evenings of meeting to be anticipated with no little pleasure.

Owing to the universal readiness on the part of the members to accede to the wishes of the Committee, and their generous exertions in providing material for the meetings, the labours of the Committee have been few and light.

As finance is a subject of importance, your Committee deems it a duty to inform you that the expenditure for the past year exceeded the income by a few shillings; and as this has been caused by the non-payment of the subscription of two members, the Committee has passed the following resolutions, with the hope of avoiding loss, and increasing the advantages of those members who may be induced to join the association late in the session:—

"That the subscription of ten shillings and sixpence per annum being due on the 31st of March, and payable in advance, should be paid to the secretary before the 28th of April next ensuing, and that the delivery of the Journal be discontinued to those members whose subscriptions are in arrear on that day; but on the payment of the same any time during the current year, the back numbers of the Journal shall be forwarded.

"That a member elected any time during the year be entitled to the numbers of the Journal from the 1st of April inclusive."

The balance in the hands of the treasurer, after payment of all liabilities of the association to the present time, is £8, 17s. 11d.

The following is a list of the papers read at the meetings held during the past session:—

March 30. By W. Hislop, Esq., F.R.A.S.—*A description and exhibition of a Lantern for illustrating lectures, &c., by means of transparent positives on glass; for the enlargement of microscopic objects, and for other purposes.*

April 27. By D. W. Hill, Esq.—*A Modification of Maxwell Lyte's Meta-gelatine Process.*

May 25. By W. Hislop, Esq., F.R.A.S.—*Remarks on the Preparation of Dry Plates.*

Sept. 28. By Dr. R. L. Maddox.—*The Parafine Paper Process.*

Oct. 26. Dr. Ryley gave *The Result of some Further Experiments on a Modification of the Collodio-Albumen Process*, which gave rise to a discussion on the merits of the dry processes generally.

Nov. 30. By G. Wharton Simpson, Esq.—*On the Positive Collodion Process, with some Remarks on the Alabastrine Process.*

Dec. 28. By A. J. Melhuish, Esq.—*On the Metal Camera.*

Jan. 25. By C. J. Hughes, Esq.—*On Toning with Alkaline Chloride of Gold.*

Feb. 29. *Discussion on a Letter by C. Oakeshot, Esq., of Ryde. Subject, Gold Toning.*

The Committee is of opinion that each member might enhance the prosperity of the association, by making its advantages more generally known; and with increased numbers benefits would accrue to all.

Your Committee would not let this opportunity pass without recording its sense of obligation to those gentlemen who have kindly read papers, exhibited apparatus, and taken part in the discussions at the meetings; and also to Mr. F. Bedford, for the liberal terms on which he supplied the Presentation Photograph.

Your Committee again assures you that it will avail itself of every opportunity of increasing the advantages of the members, and rendering the association worthy of the rank it has attained in the photographic world.

THE TREASURER IN ACCOUNT WITH THE NORTH LONDON PHOTOGRAPHIC ASSOCIATION, 28TH MARCH, 1860.

Audited and found correct, W. MORLEY. D. W. HILL, *Treasurer.*

Moved by Mr. Goslett, seconded by Mr. Dawson, that the report and statement of accounts now read be received and adopted.

The officers and existing members of committee then retired from office, in accordance with the rules of the society, and the following were elected to serve during the ensuing year, viz.:—

President.—Charles Woodward, Esq., F.R.S., J.P.
Vice-President.—G. Shadbolt, Esq.
Treasurer.—D. W. Hill, Esq.

Committee.

Mr. T. A. Barber,	Mr. W. J. C. Moens,
„ A. Goslett,	„ W. Shave,
„ C. J. Hughes,	„ G. W. Simpson.

Hon. Secretary.—Mr. John Barnett, 9, St. Peter's Terrace, Islington, N.

Some very well manufactured glass dishes, baths, and dippers were exhibited by Mr. Goslett. These were of a *hard* kind of glass, and extremely convenient in form, and were stated to have the additional recommendation of being cheap.

Mr. Hannaford exhibited a portable camera for plates eleven inches by nine, and having an arrangement for producing the effect of a swing-back by adjustment of the front in one direction, and the back at right angles thereto; also a compact folding stereoscopic camera, with movement for instantaneous exposure, by Mr. Clark, of Kennington, and Messrs. Squire's pocket camera, for stereoscopic pictures.

Mr. Goslett exhibited a series of specimens of glass adapted for photographic purposes, viz.:—Flatted crown, patent plate, patent plate roughed, colourless patent plate, opal, opal roughed on one side, yellow, orange, ruby, black, light blue, and sky blue; also a piece of photographic paper exposed under various coloured glasses, showing the effects of retardation of the actinic rays.

A desultory discussion then ensued on the application of the various kinds of glass, and the changes they undergo by exposure to light, in which Messrs. Goslett, Quin, Hughes, Wall, Hannaford, and others took part.

Mr. G. Wharton Simpson asserted that a lens that he had in use for some years had become decidedly slower in action, possibly in consequence of the changes in colour of the glass of the lens arising from exposure to light.

Mr. Hughes and Mr. Quin both objected to the use of *smoothed* glass, (as it is termed), as being almost impossible to clean properly.

Mr. Goslett stated that, by using the finest washed emery between two pieces of *smoothed* glass, rubbing them together, and copiously washing with water, the *smoothed* glass can be readily and perfectly cleaned.

Mr. Hannaford then made some remarks upon the subject of "burning in" photographs upon glass.

Mr. Goslett related an instance in which some common German glass had been used for glazing a picture-frame in which an engraving was preserved, and that an image of the engraving was subsequently found to be impressed upon the glass.

Mr. Wall, in taking a coloured photograph from a passe-partout, found that, on breathing on the glass, a faint image of the picture was left behind.

Mr. Goslett inferred, that both these examples demonstrated the inferior quality of the glass employed, which probably contained an excess of alkali in its composition.

Mr. Dawson referred to that part of Mr. Oakeshot's letter, published in our last number, relative to the experiment of MM. Davanne and Girard, on fixing positive proofs. He stated that, being by no means satisfied of the

correctness of the observations made by these gentlemen, he had gone through a series of experiments as follows:—

Having dissolved ninety-six grains of hyposulphite of soda in half an ounce of water, and precipitated chloride of silver, by means of common salt, from the nitrate of that metal which he washed and dried, he dissolved five grains of the latter in the half-ounce of solution of hyposulphite before mentioned, the solution being perfectly effected in the space of *two minutes.* Having waited for about ten minutes, he dissolved in the same solution four more successive quantities, of five grains each, of the chloride of silver, which took as follows to dissolve, viz.—

2nd ....Five grains in 2 minutes.
3rd .... " " " 2 "
4th .... " " " 2 minutes and 10 seconds.
5th .... " " " 2 " " 15 "

The whole was then left in repose for twenty-four hours, without any deposit being formed. He then added *four more* successive quantities of chloride of silver, each of five grains, when the

6th......Five grains dissolved in 2 minutes 30 seconds.
7th...... " " " 3 "
8th...... " " " 4 " 30 "
9th...... " " only about half of it could be made to dissolve, but the hyposulphite of soda had then taken up *nearly half its own weight* of the chloride of silver.

On stirring with a glass rod, a white precipitate was thrown down, which, on removal from the liquid, was found not sensitive to light.

The solution was then evaporated in a porcelain capsule over a sand bath, maintained at about 180° Fahrenheit, when it changed to a dark colour, and precipitated a brown powder.

During all the experiments, a piece of litmus paper (one half reddened) was kept in the solution; but neither acidity nor alkalinity were manifested, excepting during the evaporation, when decided acidity was displayed. Mr. Dawson concluded by expressing his conviction that Messrs. Davanne and Girard were decidedly wrong in their statements.

Mr. Dawson stated that, in consequence of some remarks upon ammonia fixing, by the Vice-President, at a previous meeting, he had tried some experiments with it, and found that, as asserted, albumen, after the action of the nitrate of silver, was not soluble in the ammonia. He exhibited a number of proofs perfectly fixed by both methods, and could detect no difference between them. He had tried a rough experiment relative to the solvent power of the common liquor ammoniæ for chloride of silver, in a similar way to that employed for the hyposulphite of soda, and found that, in half an ounce by measure of the liquor ammonia, the

1st ....Five grains dissolved in 2 minutes.
2nd .... " " " $2\frac{1}{4}$ "
3rd..................... " " " $3\frac{1}{2}$ "

And that this last addition exactly saturated the liquid.

Votes of thanks were then passed to Mr. Goslett, Mr. Hannaford, and Mr. Dawson, and after a protracted but highly interesting sitting, the meeting was adjourned till the 25th instant.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of the above society was held on Thursday, the 15th ult.,—the Rev. F. F. Statham, F.G.S., President, in the chair.

The minutes of the last meeting having been read and confirmed,

The Secretary said he had to thank Mr. J. A. Forrest, of Liverpool, for calling his attention to the contemplated Exhibition of Photographs, in connection with the Liverpool Society of Fine Arts. This was, he believed, the first exhibition of paintings at which specimens of photography had been admitted, and he should be glad to see the art which produced them so represented at this exhibition as to prove it worthy a place beside its sister art—painting.

A report from the committee was then read relative to the organisation of a Photographic Exchange Club, expressing a desire to place the arrangements upon a good working foundation. It had been suggested that the members of the club should not necessarily be members of the society, but that all who were willing to pay a nominal yearly fee to cover the expenses of postage and stationery should be admitted, and that a competent secretary be appointed, through whom only exchanges between members and non-members should be effected, in order that no specimens might be exchanged but such as were of comparatively equal value. Those joining this club would be required to place specimens of their ability in the folio, with their name, address, and the words "for exchange" attached.

Some conversation upon this subject then ensued, in the course of which it was suggested by Mr. Hannaford that it would be advisable to rule that each party merely pay the cost of transit, instead of establishing a definite yearly payment; and by Mr. Wall that all our societies might combine for the purposes of exchange, and by so doing establish a connecting link between each and every organised body representative of the photographic community throughout the three kingdoms. He thought that a social feeling of kindly intercourse never failed to benefit all concerned. Eventually, at the suggestion of the Chairman,

Mr. Stevens moved, and Mr. Fitch seconded, that a vote of thanks be tendered to the committee for their report, and that they be requested to carry out the proposed arrangements.

This motion was carried *nem con.*

Mr. M. Hannaford then read the following short and very interesting paper, illustrating it practically as he did so, and exhibiting specimens. This was given as a continuation of the

PHOTOGRAPHIC JOTTINGS.
No. 4.
On Iron Printing.

After some few remarks, and one or two introductory experiments, Mr. Hannaford said:—The process I am about to describe was made public by me last year, at a meeting of the North London Photographic Association, and I have but little further that is new to add now, excepting some details of manipulation. I will, however, very briefly recapitulate.

Float French paper on the following sensitising solution, and hang by one corner to dry in the usual manner:—

Albumen.........................	1 part	1 ounce.
Water	1 "	
Ammonio-citrate of iron....about	50 grains	
Bichromate of potassa ....to saturation		

The time of exposure will be rather longer than for silver prints, but not materially so. The picture should appear of a brown ochre colour, on a yellow ochre ground, showing details and half-tones as fully as an ordinary silver print.

Well wash to remove the iron from parts not acted on by the light, and darken by saturated solution of gallic acid.

This is the process in its simplest form; and I will now add a few instructions for obtaining a variety of tones, and also some hints that may be of use in manipulating.

Gold Tones.—Expose and wash as before. Then immerse the print for two or three minutes in chloride of gold half grain, water one ounce. Wash thoroughly and darken by gallic acid. By immersion in a very weak solution of iodide of potassium a variety of pinkish tones may be obtained. The colours of these prints are by no means so brilliant as those of the gold-toned silver ones, but they are quite equal to the tones got by the old sulphur bath without gold.

Blues, Greens, &c.—For Prussian blue prints proceed as in the last case, but using solution of ferro-cyanide of potassium instead of gold. On development by gallic acid the picture will appear of a blue-green, which may be converted into a bright Prussian blue by weak solution of hydrochloric acid, a few drops to the ounce of water.

Red prussiate of potash used instead of the yellow prussiate, gives a good blue black, which hydrochloric acid converts into a dull blue.

A solution of borax poured over a Prussian blue print very materially deepens the colour. Gum arabic, mixed with the sensitising solution, tends to give a ferro-cyanide picture a decidedly green tint; but when simply developed by gallic acid, the resulting positive is of a dark bistre tone, not in anyway partaking of "inkiness." Gum arabic, however, is by no means a good size to employ, as the picture is very apt to wash off from some portions. If gelatine be employed, no amount of washing seems to remove the unsolarised iron thoroughly, even though hot water be used. Foreign starch-sized papers are, therefore, far better than the English, which contain gelatine. When, however, albumen is used as I recommend, the prints will bear any amount of rough washing, and for any length of time.

The greatest difficulty to overcome is the slight—very slight—discolouration of the whites, to about the same extent as in developed silver prints. The plan I adopt is to immerse the picture in a weak solution of carbonate of soda, ammonia, or acetic acid. The alkali produces a not over agreeable red tone, while the acid does not materially change the tint.

The President thought very highly of this interesting and exceedingly economic process, and inquired whether Mr. Hannaford had used any of the alloys of iron? A variety of tints might also be obtained by the use of gaseous vapours, and he recommended Mr. Hannaford to pursue his experiments in this direction; since, although the results at present obtained might not compare with the better understood silver process, there was evidently much of promise and encouragement to be found in the specimens before them. After some other remarks,

Mr. Hannaford said he had not tried alloys, but he thought it possible to obtain many of the other colours named by the President, viz., the ruby-red, by mercury—the silver-grey, by gold, &c. He intended to pursue his experiments in printing with copper, and also hoped to lay before the society some further experiments in the iron process. In conclusion, he paid a well-merited compliment to Mr. Hunt, whose experiments, he said, originated nearly all these new processes.

Mr. F. Howard said he had not the knowledge of chemistry which would enable him to aid the present discussion, but it had struck him that a process so very inexpensive, and producing such a variety of beautiful colours, was calculated to afford some assistance to manufacturers requiring patterns.

Mr. Hannaford believed that the process had its foundation in that of calico printing.

Mr. Wall would ask Mr. Hannaford if there was any reason why these iron pictures could not be produced upon ivory. A series of experiments, which were tried at his establishment some time back, led him to suppose that the few pictures upon ivory which might be called suc-

cessful were certainly not produced by the usual silver process. [Mr. Ackland here whispered to the Secretary that they certainly were.] Seeing that ivory was a composition of gelatine and phosphate of lime, the difficulties to be encountered were apparent at once; but he was led to make the inquiry by remembering that all who had produced good pictures upon this surface had practised and experimented in the iron printing, and that some of the colours in the specimens before them closely resembled those he had seen upon ivory.

Mr. Hannaford thought he should find little difficulty in obtaining iron prints upon ivory, and had no doubt of being able to produce a good specimen on this material at their next meeting.

Mr. Statham inquired if the colour of the iron prints changed at all when removed from the bath?

Mr. Hannaford said they did not.

Mr. Wall, in reply to an inquiry, said the colours produced by iron printing closely resembled those in which most of our best painters first laid in their subjects, and were therefore especially adapted for the purposes of colouring, with the additional advantage of undoubted permanence.

A vote of thanks having been awarded to Mr. Hannaford by acclamation, the President called upon the Secretary for his promised "jotting."

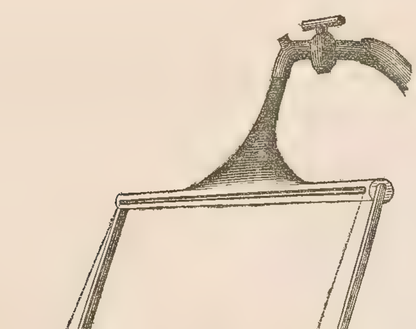
Mr. Wall then read the following short paper:—

PHOTOGRAPHIC JOTTINGS.
No. 5.

On Photographic Print Washing.

A lengthened immersion in water is now very generally admitted to be injurious to the more delicate tones of the photograph, and yet we readily acknowledge the vital importance of removing every trace of hypo from the paper. I do not think the time of washing can be very materially shortened by the ordinary process without great danger, and as a proof of this I may venture to describe an experiment recently tried by Mr. G. W. Simpson. Professor Taylor having provided him with a very delicate test for the hyposulphite, he used it in the last water in which a print, previously washed by the ordinary means for twenty hours, had been placed, which print, I should say, had also been subjected to the action of boiling water; upon doing so, a brown sulphureous precipitate was immediately formed, proving the existence of the destructive agent in a very decided manner, even after this lengthy treatment with repeated changes of water. A constant and thorough changing of the water, and the continual movement of the prints, had been secured by several mechanical contrivances, but even thus aided the prints were found to have been too long in the water. The speed and certainty of the washing process being therefore a matter of importance, every hint becomes of some value, and he should not hesitate to occupy a few minutes in describing a machine by which the prints were subjected to a variety of cleansing actions by water, viz., by the water running *over* the surface of the paper, penetrating *through* the paper, and acting upon *the back and front* of the paper at the same instant of time.

MR. WALL'S PRINT-WASHING APPARATUS.



Procure, in the first place, a length of piping, regulating its diameter and length according to your supply of water or the work it has to do; make a narrow opening along its entire length, one end of which is turned over to form a kind of lip. The holes at either end must be securely fastened up. To the centre of this piping, and exactly opposite the long aperture, attach another smaller pipe of about two or three feet in length, opening into the first pipe through a long mouth gradually widening to the entrance into the larger pipe, the other end of which is so contrived that it will screw, with a nut, to a water tap for the admission of water.

The next article required is a long cylinder or drum of some stout but porous material, such as rather close webbing, stretched upon a very light cane frame made to revolve upon two pieces placed at either end. This is then attached to the pipe with the long aperture at a distance of about three feet, and the tap being turned on above, a sheet of water falls from the opening upon the drum below, causing it to revolve.

A number of prints being fastened upon the drum are, as I have said, washed above and below, in front and behind at the same time, the water passing completely through the cylinder and prints. The rotatory motion can be quickened to a great extent by attaching a small light water-wheel to one end of the drum, and the waste water may also be preserved by falling into a tank or sink below.

There was not, as some might suppose, the slightest danger of injuring the fabric of the paper by this method; for to test this he had subjected a piece of blotting paper to the action of the falling water, descending from a greater height than that mentioned, for many hours without injury.

The President said that, like a great many other things, this process, though simple in character, was yet of the utmost importance. The adoption of a water-wheel seemed to be useful; but he thought Barker's arrangement would be a better one (by which a small stream of water did the work of a very much larger quantity).

Mr. Hannaford thought Mr. Wall's process of washing a very good one. The hyposulphite, although in itself a very soluble salt, was removed from paper with very great difficulty, and he did not know any better illustration of this than that afforded in practising the iron process.

Mr. Howard thought the hypo could be removed without the prolonged washing so frequently recommended if the prints were carefully treated. Much less washing was necessary when using the alkaline bath. The hypo should be fresh each time.

Mr. Herve had some prints which had remained unchanged a very long time, and he attributed the fact to the use of a brush in the washing process. He thought the real permanence of photographs would never be secured by any process but a chemical one; but he was going to make some experiments in this direction, and would on some future occasion acquaint the society with the results.

The President suggested a chemical solution for the removal of the hyposulphite. The dispersed atoms retained in the paper would adhere too closely to be removed by any gentle action of washing; and Mr. Hervé might justly, perhaps, attribute the comparative permanency of his productions to the use of the brush. In that case the mechanical abrasion obtained by Mr. Wall's method would undoubtedly prove effective, acting as it did upon every portion of the paper simultaneously with much force and vigour.

Mr. Leake had never found the tones of his prints toned by the alkaline gold bath injured by prolonged washing. He recommended the use of a sponge, but thought not less than twenty-four hours' washing would secure the print from fading in a very short period.

Some discussion ensued upon the use of ammonia, &c., which was continued so long that a third "jotting," by Mr. Clarke, upon a few experiments he had made with the various salts of silver was necessarily postponed.

A vote of thanks was passed to Mr. Wall.

A paper by Mr. F. Howard, upon *Photography from an Amateur's Point of View*, was announced by the President, who also promised a paper upon *Photography as Allied to Science* for the meeting after the next.

An enlarged photographic copy was presented for the folio by Mr. F. Howard. A new pocket binocular stereoscopic camera, with an ingeniously contrived, though very simple, method for taking instantaneous pictures, was exhibited by the inventor and manufacturer, Mr. W. Clarke. The Society's presentation print was also distributed, and elicited much approbation. The meeting was then adjourned.

BLACKHEATH PHOTOGRAPHIC SOCIETY.

The twenty-third ordinary meeting of this society was held on Monday, the 19th ult., at the Golf Club House,—the President, J. Glaisher, Esq., F.R.S., in the chair.

The minutes of the last meeting having been read and confirmed,

Mr. Charles J. Busk proceeded to read a paper *On the Reproduction of Engravings, Prints, Ordinary Writings, or Letterpress, on Prepared Papers, by Contact in the Dark.* [See page 98.]

A cordial and unanimous vote of thanks was tendered to Mr. Busk for his interesting communication.

The President then said:—You are aware that the Collodion Committee appointed by the London Photographic Society has made its report. I have read the report with some surprise; and, as I think it is the duty of societies like our own to do all in their power to prevent those who are looked upon by the public as photographic guides from leading them astray, I shall call upon Mr. Heisch to make some remarks on the report.

Mr. Heisch said:—Sir, in March 1859, the Photographic Society of London appointed a committee to examine collodions, with a view, as stated in the report before us, of arriving at a definite formula.

The report of that committee was to have been discussed at the last meeting of the society: all who were present will remember how abruptly the discussion was concluded.

It is not, however, to comment on this subject, nor on the strange position in which a society places itself by appointing a committee to examine and report on an important subject, and when that committee makes its report, neither adopting, rejecting, nor even discussing its recommendations, that I now come forward. Had the committee confined itself to matters in which only the society appointing it was concerned, I would not have been the one to meddle in other men's matters. I should not have said one word to-night did I not feel that a great injustice has been done to the public in general, and the manufacturers of collodion in particular, by the wording of this report. I acquit individual members of that committee of any intentional injustice, but that injustice has been done I fearlessly assert.

Sir, the report of the committee states that the collodion made by Mr. Hardwich is, "in regard to sensitiveness, unsurpassed." That "it is of superior excellence," and they "confidently recommend the society to stamp it with the full mark of its approbation." Sir, if these words mean anything, they mean that in the opinion of the committee this collodion is more sensitive and altogether better than any other in the market.

Now, sir, there are hundreds of people, who have neither time or inclination to examine various samples of collodion for themselves, who will receive this as an authoritative judgment, and will not even take the trouble to examine the report, and find out—what would surprise any one who reads the words quoted—that the collodion in question was never compared with any other; and, moreover, that the facts concerning its working properties detailed in the report form but a very slender foundation for such unqualified praise. Makers of collodion will naturally feel delicate in protesting against this report, and it is on this account that I feel that we, who are neither makers or vendors of collodion, ought to come forward and protest against a society, supposed to be the leading photographic association in England, putting it into the power of any tradesman to use its name in proclaiming the superiority of the article he sells, more particularly when we consider that the article in question has not been compared with that of other makers.

I will now say a few words on the report itself to justify the observations I have made.

First, we are told that the collodion is "comparatively, if not entirely, free from glutinosity, crapy lines, contractility, and other defects of film, met with some years back." Now, sir, I would ask, with what has it been compared? Certainly not with any of the first-class collodions in the market, many of which are *entirely* free from any of these defects.

Next, we are told that it "sometimes contains too much soluble cotton for large plates, and occasionally requires thinning down in hot weather. These words "sometimes" and "occasionally" are very significant, showing, as they do, that the collodion is not always alike. Another proof of want of uniformity is, that Mr. Fenton states that on using some of the earlier samples of the collodion he was obliged to roughen the edges of his largest plates to prevent the film from curling off, but that with subsequent samples it was unnecessary. Were these last samples made according to the formula originally sent to the committee? If so, it is clear its results are not always uniform; if not, it cannot be called the same collodion.

Next, we are told of a tendency to irregular drying. This, however, is said to be inconvenient, but not insuperable.

We now come to its sensibility, which we are told is, in the opinion of the majority, "unsurpassed." To justify this expression it should have been compared under the same conditions with every other collodion, which there is no pretence even that it was by the majority, while the only member of the committee who compared it with any other found that it took double the time. An attempt is made to explain this by the fact of his using a weak developer; but as we may fairly presume he used the same for both collodions, the explanation is far from satisfactory. Mr. Frith's private letters are here pressed into the service, but they will not do much towards proving the unsurpassed sensibility of this collodion with those who have seen the instantaneous pictures of Mr. Lake Price and others, taken with other collodions, not in the clear light of Cairo (which contains, according to the careful experiments of Bunsen and Roscoe, more chemical rays than the light in any other part of the world yet examined), but in London—not on four and a half inch plates, but on twelve inch plates.

With regard to keeping properties, unless iodised with cadmium it loses its sensibility in two or three days in warm weather—no slight defect in most people's opinion!

In speaking of the gradation of tone in the pictures produced with the collodion, after many rather contradictory remarks, the committee conclude that it is "sufficiently good." Sufficiently good for what purpose?

One gentlemen next speaks of transparent spots with tails, and two or three, of fine black lines. Curious defects in a collodion to be stamped as of superior excellence by the Photographic Society!

One point mentioned by Mr. Fenton strikes me as very remarkable, viz., that when used with the addition of bromide it will not bear the least over-exposure. With all collodions which I have tried bromides enable them to bear a much greater amount of exposure without injury.

I cannot but remark that, though three formulæ were sent in, not one word is said of two of them; and the gentleman charged with examining them, only says he assisted at the preparation of Mr. Hardwich's collodion, but does not say whether he succeeded in preparing it without that gentleman's assistance.

Now, sir, let me sum up the facts of the report.

1. The film is not quite structureless.
2. Its properties are not quite uniform.
3. When compared with other collodions it was not so sensitive.
4. It has no keeping properties unless iodised with cadmium.
5. There are complaints of transparent spots and dark lines.
6. When bromised it soon solarises.

Yet this collodion is to be stamped with the approbation of the London Photographic Society as of superior excellence, and unsurpassed sensibility! If I could believe such a thing possible, I should be inclined to say that the committee must have furnished the facts, while some other individual has drawn the conclusions.

I beg to have it understood that I offer no opinion on the merits of Mr. Hardwich's collodion: I point out only the discrepancies of the report.

I am perfectly aware that much of what has so strange an appearance may be capable of explanation; and I have made these strong remarks to-night, partly with a view of giving the committee that opportunity of explanation which was denied them at their own society.

The injustice to other collodion makers cannot be explained away, and it is against this that I wish our society to protest; but this unfavourable impression so commonly, I may say so universally, entertained of the report itself, may, I trust, be at least partially removed. At the same time I cannot but remark that Mr. Hardwich's letter, published in the last number of the *Journal of the Photographic Society*, will rather increase than diminish that unfavourable impression. Mr. Hardwich puts himself prominently forward as the champion of the report, forgetting that he is not one of those who signed it, and is therefore not answerable for its contents, and forgetting also that he is the manufacturer of the article which is reported on.

After some remarks to the same effect from other members of the society, Mr. H. Williams proposed and Mr. J. T. South seconded the following resolution, which was carried unanimously:—"That the remarks of Mr. Heisch be adopted as expressing the opinion of the society."

The meeting was then adjourned.

PHOTOGRAPHIC SOCIETY OF SCOTLAND.

The ordinary monthly meeting of this society was held in George Street Hall, Edinburgh, on the evening of Tuesday, the 13th ult.

The chair was occupied by Sir David Brewster, President of the society. The following gentlemen were admitted by ballot, as members:—Messrs. P. Stewart, R. Cowan, R. Romanes, W. Younger, J. L'Amy.

The Secretary read a paper *On Composing and Printing Single Photographs from Several Negatives*, by Mr. H. P. Robinson, of Leamington, to whom was awarded one of the Society's Medals for the best group in the Exhibition. [See page 94.]

There was no discussion on Mr. Robinson's paper.

Mr. Macnair gave a more detailed account of the process for preserving the sensitiveness of collodion plates, which he had discovered a few months ago. This process, he said, consisted, in brief, in coating an excited and washed collodion plate with an infusion of malt, which was dried by the application of heat, and, after exposure, the plate was developed by a solution of sulphate of iron, the preservative solution having been previously removed by copious washing, and the plate wetted over with a solution of nitrate of silver, by immersing in the bath for a short time. The negative might not be dense enough to print from in this state, but density might be attained by pyrogallic acid and nitrate of silver employed in the usual way.

In the course of some interesting remarks on the changes grain underwent in the process of malting, he stated that the malt in a dry state contained gluten, gum, starch, and a sugary matter which did not crystallise, and which he believed could not be crystallised without sulphuric acid, or by some other chemical process; that when an infusion of ground malt was made at a proper temperature, a rapid conversion of the starch, as well as nearly all the gluten and gum, took place, and the whole was changed into a new sweet matter; that the conversion could be checked at any stage, and that the best state for the purpose was when the infusion, when dried upon the plate, was least deliquescent, and contained only sufficient quantity of this grape sugar to allow it to be readily washed off the plate after exposure.

He concluded by saying that a few ounces of malt would make an infusion sufficient to coat some dozens of stereoscopic plates, as three ounces would make fully half a pint.

Mr. Macnair showed several specimens of negatives and transparencies taken by this process, which were much admired.

Mr. Orange said that he had, at the request of Mr. Macnair, wrought a good deal by this process of late, and he could speak very favourably of it. He exhibited some pictures as illustrations of its capabilities, and, in answer to a question, said that it was necessary to use the wort while new, as it did not keep long.

Dr. Walker said he also had tried it, and although he did not think it

would supersede other processes, yet he thought its simplicity and certainty would recommend it to many. He had recently, on a visit to Dumfries, exposed some plates which Mr. Orange had prepared for him, and which he exhibited. [Dr. Walker's negatives displayed great artistic skill.] The exposure, he said, was not much longer than he would give a wet collodion plate.

Dr. PATTERSON said that, seeing the many changes which took place in the process of malting, and the great difficulty of procuring two specimens of wort which should be alike in every respect, he thought that the best way would be to make an analysis of that sample which should by experiment be found best adapted for the preserving of collodion plates.

This was unanimously agreed to.

After some remarks from Mr. NICOL on the chemistry of wort, and the peculiar changes the grain underwent in malting,

Sir DAVID BREWSTER brought Mr. Skaife's Pistolgraph before the notice of the meeting.

The subject of instantaneous pictures elicited a discussion between Sir David and Mr. J. T. Taylor, in which the latter defended large lenses, and the former denied the possibility of producing by the lenses ordinarily employed in portraiture, pictures which could at all lay claim to accuracy.

Sir DAVID BREWSTER also called attention to the fact that Mr. Skaife had patented a process for protecting the film by enamel. This he did by covering the glass photograph by a plate of glass, and subjecting the whole to a considerable heat.

Mr. TUNNY (examining a specimen which Sir David had handed to him) said he rather thought that the surfaces of the two plates were not throughout in entire contact, but that such contact was confined to the edges alone; but if Sir David would allow him, and risk the destruction of the picture, he (Mr. Tunny) would endeavour to separate them and see if he were correct in his surmise.

Sir David consenting, Mr. Tunny inserted the edge of his knife between the two surfaces, and found that it was as he had anticipated.

The meeting separated at the usual time. There was an average attendance.

LIVERPOOL PHOTOGRAPHIC CLUB.

THE usual meeting for the month was held at the residence of Mr. Forrest, on the 13th ultimo.

Mr. COOK exhibited some very highly interesting views, belonging to Mr. Pooley, representing all the horrors of the Arctic seas. They were the work of Doctor Walker, who had accompanied the expedition of Captain Sir L. M'Clintock, in the *Fox*. Photography in these hyperborean regions must be pursued under difficulties indeed; and the public are much indebted to the spirited operator who so perseveringly prepared for their gaze such faithful presentments of those dreary scenes, regarded with the painfully wrought interest that all have felt for everything that relates to the late lamented Sir John Franklin. As an apt accompaniment to these melancholy evidences of the fearful past,

Mr. KEITH exhibited some very well-executed views he had just taken at Moelfra, so celebrated for the fearful wreck of the Royal Charter. One was a very lively picture of the adjacent village, and another, the present scene of the late frightful calamity. The recent low tides had revealed, as it was expected they would, more of the remains than had ever before been seen, and thus was shown so accurately by the camera all the terror of the place that the inevitable fate of the doomed ship could be well judged by this view. A more fatal spot on this iron coast could hardly present itself, and yet a little more than her own length on either side of this tongue of rocks might have prevented the dread sacrifice.

Mr. COREY commented on the omission of all mention of a valuable contribution of Mr. Cauty's, at the last meeting. This was a photograph of a patient in one of the infirmaries, who had a very extensive and strongly-marked dislocation of the hip-joint. The head of the thigh-bone was so much displaced as to be firmly imbedded in the hollow of the *ossa innominata*, so that the heel of the foot was turned directly outward, and the toe, consequently, pointing to the inner *malleolus* of the other foot. This was a highly useful and instructive application of the art of photography, as it would enable students, and even adepts, in the healing art to recognise the nature of the injury in future cases at a single glance.

Mr. CAUTY stated also that he had had signal success with plates prepared as recommended by the Abbé Despratz, viz., the addition of one-third of a grain of fine common resin to each ounce of collodion. This entirely superseded the use of any preservative medium, if we except slightly washing each plate twice.

Mr. Glover, in apologising for his absence, sent a letter, speaking in terms of strongest praise of the mode of printing by the method recommended by Mr. Maxwell Lyte. Its chief qualifications, he thought, were its simplicity; its being ever ready for immediate use; its freedom from stains; and there being no necessity for heating, as in the rival process of Mr. Hardwich. At the risk of repeating an oft-told tale, the formulæ he uses are those advised by Mr. Shadbolt, viz:—Take of

Phosphate of soda	30 grains.
Chloride of gold	1 grain.
Water	8 ounces.

Dissolve in equal proportions of water and mix. Sufficient for four pictures eleven by nine inches.

At the close of an extremely social and very intellectual evening, it was decided to hold the next meeting at the residence of Mr. Keith.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

The Wet Process v. *The Dry.*

ON Tuesday evening, the 27th ult., the monthly meeting of the above society was held, and the attendance of members and friends was more numerous than usual, owing to the interest taken in the friendly tournament got up between the advocates of the wet and the dry processes. It originated in a paper communicated to the society by Mr. Shadbolt, the editor of this Journal, in which certain phenomena connected with the use of Dr. Norris's dry plates were incidentally referred to. During the conversation which ensued, Mr. Charles Breese, a gentleman whose very fine works have been seen by few besides his friends, dropped an opinion that none of the dry processes were equal to the production of a really good artistic picture. He admitted that he had never used the dry process, and had seen comparatively few proofs of what it could produce, but he considered that those he had inspected justified the opinion he had expressed. To use a sporting phrase, Mr. Breese was challenged to "back his fancy," and Mr. W. B. Osborn and other "dry" professors undertook to do what they could on behalf of Norris, Fothergill, and Coy.

Mr. Haines occupied the chair on Tuesday evening; and Mr. OSBORN, having briefly explained the origin of the friendly "trial of strength," Mr. BREESE produced a collection of his own pictures, as proofs of what could be done with the wet process. These, thirty or forty in number, embraced views of the sea in some of its most opposite aspects, photographs of cloudland, moonlight scenes, a view of the recent eclipse of the moon, street views taken during the Queen's visit to Birmingham, architectural photographs, waterfall pictures, &c. Some of these were included in the fine series which Mr. Breese had the honour of sending to the Queen, by Her Majesty's commands, in the winter of 1858, and which were at the time described in the Journal. Independently of the combination of skill and scientific knowledge which enable this gentleman to portray clouds of all complexions and sizes, to suspend a wave in mid air, and give us its likeness as its foaming crest is dashed back by the land breeze, to transcribe faultlessly the life and bustle of a town *en fête*, to work with his camera when the sun is shining on New Zealand, and when even Luna herself is half extinguished—independently of these rare qualities, the gradation of tone and sense of distance which his pictures possess were admitted to be as nearly perfect as anything the art of photography has yet produced: all were instantaneous stereoscopic pictures on glass. While the wet process was thus worthily represented, the merits of the dry process were also supported by a large number of first-class specimens, contributed chiefly by Mr. Osborn and Dr. Hill Norris. The collection shown by the former included an album of large pictures, taken by the Fothergill process, and kindly sent for the occasion by Mr. S. Bourne, of Nottingham. Mr. Breese's objection to the dry process was, that he had never seen any which gave sufficient atmosphere and distance; but some of Mr. Bourne's pictures seemed all that could be desired in both respects. As regards distance, the *Views of Windermere* and *View from Lancaster* and *Tintern Abbey* were especially noticeable, the half-tone and fullness of detail in the latter being very satisfactory. In half-tone effects *Audlem Church*, Cheshire, and *Lincoln Cathedral*, might be said to be perfect, and *Milford Church*, Notts., was not far behind, while the *Views of Dovedale* gave atmosphere in perfection. Mr. Woodward, of Nottingham, also sent a collection of stereoscopic paper slides, by the collodio-albumen, including some of the finest "dry" works we have ever seen. For half-tone his *Jedburgh Abbey*, *Fountains Abbey*, and *Cottage at Milford*, were much admired, as was also his *Peterborough Cathedral* for distance; and a beautiful scene, with water, taken in Burghley Park, was admitted to be perfection itself. Dr. Hill Norris contributed some twelve by ten inch pictures, which were very good, and a number of exquisite transparencies, by his process, which were pronounced equal to any wet plates yet produced, except the instantaneous ones—his *York Minster* being pronounced the best. Mr. Seymour, Mr. Bright, and Mr. Applewhaite, of Leamington, contributed several very good negatives by the Fothergill process, the latter gentleman showing one taken in sixteen seconds. Mr. Osborn's were greatly admired, being all by Dr. Hill Norris's process.

The various pictures having been carefully examined by the meeting, Mr. OSBORN remarked, that the comparison which had that evening been instituted between "wet" and "dry" was scarcely a fair test, because he did not know any photographer who had ever produced anything equal to what Mr. Breese had shown them. It was not contended, for instance, that dry photography would produce instantaneous pictures, though he hoped the time was not far distant when this would be done. But the dry pictures they had been inspecting proved that both distance and atmosphere could be produced by competent men. The great advantage claimed for dry photography over wet was, that in using it photographers were not obliged to encumber themselves with a great amount of heavy apparatus, and were thereby less liable to suffer inconvenience from forgetting to take with them some trifling but very necessary part of it. Wet photography, too, often made a toil of what should be a pleasure. He did not believe that dry photography would ever entirely supersede

the wet; but he was prepared to contend that the pictures he had shown, especially those of Mr. Bourne, were not only *quite* equal to any of the ordinary wet collodion photographs, but superior to many from their abundance of half-tone, general pleasing effect, and clearness and freedom from spots.

Mr. Breese remarked that some of the Nottingham pictures showed that where they got the best distance they had the worst foreground.

Dr. Hill Norris asked whether Mr. Breese was of opinion that if the dry process were equally rapid with the wet, the results obtained would be equal?

Mr. Breese: No; I do not think the dry can copy the atmosphere as delicately and truly as the wet.

Dr. Norris: As a chemist I cannot see why there should be any difference, as in both cases the light has the same sensitive material to act upon. I think that if we can make the dry process as rapid as the wet, we shall certainly succeed in securing the whole effects Mr. Breese has shown us to-night; and I am very sanguine that this will be done. [Dr. Norris produced some dry pictures which he had taken in from five to twenty seconds.] He remarked, as to Mr. Breese's observation about good distances having bad foregrounds, that if the sensitive material to which both were exposed were equal, it followed as a necessity that the more distant object would be the sooner printed, and that the nearer object would require greater exposure to bring it to the same degree of intensity. If a plate would bear exposure for the most distant objects without being overdone, then certainly that plate, whether it be wet or dry, is capable of rendering all the effects in the foreground.

Mr. Breese: The argument may be very good scientifically, but I do not see the result in practice. In one of the best dry pictures I have seen to-night the foliage in the foreground does not appear.

Dr. Norris: That is because the picture is not sufficiently exposed.

Mr. Breese: And yet you have the distance,

Dr. Norris: It is necessary in all cases, whether wet or dry, that the distance should be over-exposed, in order to bring up the foreground, simply because the light that comes from distant objects is concentrated into smaller space. What I contend is, that if we had a dry film sufficiently rapid, we should get as good pictures as with the wet. In comparing dry collodion with wet, you must take the productions of a host of individuals, and I dare say you will find very good and very feeble results on both sides. I certainly cannot see how the wet process can excel the dry in any other respect than that of rapidity.

Mr. Breese: Which is a very important matter.

Dr. Norris: But still we are not without hope.

Mr. Breese: No; but we are simply talking about how far the process has been carried out. Is it anywhere near the wet process at the present time?

Dr. Norris: The dry process is constantly producing results which are exhibited by old "wet" operators, without its being detected that they have changed their process.

Mr. Breese: That will depend a good deal on what the operator can produce with the wet, and would not say much for either process.

Mr. Osborn: There you are greatly in error, as the gentlemen alluded to are first-rate wet operators.

Mr. Johnstone said that, in the matter of distance and foreground, all must know that a great deal depended on the mode of development. If they tilted up a picture so that the greatest amount of fluid lay on the distance, the foreground would develop in a much greater degree than if they were to get the fluid over it. Again, in rendering a daguerreotype plate sensitive, certain definite proportions of iodine and bromine produce certain results. Two of bromine to one of iodine produced a clearly defined picture, but with a tone somewhat unusual: equal proportions gave a picture that looked as if it had not been well focussed; but if the proportion of bromine were increased to exactly three, a well-defined picture would be the result. Why should not this principle of coating be attained on dry collodion plates? Most of the compounds of collodion had bromides in various proportions, but the plates were of much the same degree of sensitiveness.

Dr. Norris: Does not Mr. Breese attribute some of the perfectness of his results to the use of bromide of silver with his collodion?

Mr. Breese answered in the negative, and, in reply to another question, said that his negatives did not take more than the tenth part of a second in their production. None of his pictures took more than five or six minutes to develop.

On the motion of Mr. Brown, seconded by Dr. Norris, a cordial vote of thanks was passed to Mr. Breese for his kindness in attending the meeting; and in acknowledging the compliment, Mr. Breese admitted that he had that evening acquired an appetite for trying what he could do with the dry process. He had certainly seen better pictures than had previously come under his notice.

Mr. Osborn moved a vote of thanks to Dr. Norris, which was seconded by Mr. Ball, and unanimously passed.

The stereoscopic pictures inspected during the evening were seen to much advantage by the aid of the new patent achromatic stereoscopes, manufactured by Messrs. Cutts, Sutton, & Co., of Sheffield. They were acknowledged to be exceedingly perfect instruments, free from the slightest distortion, and of great power.

The meeting did not break up till half-past ten.

It is expected that Mr. Sutton, of Jersey, will be present at the next meeting, and read a paper *On Panoramic Photography*.

CHORLTON PHOTOGRAPHIC ASSOCIATION.

The monthly meeting of this society was held at the Chorlton Town Hall, on the 14th ult.,—Mr. Nicholson, Vice-President, in the chair.

The minutes of the last meeting were read and confirmed, and the officers of the society for the next year were proposed.

A note from Mr. Wardley was read, stating that owing to indisposition he should be unable to attend and read the paper he had promised.

Mr. Griffiths read a paper, entitled *Observations on a Method of Enlarging and Multiplying Negatives*. [See page 96.] He also exhibited two prints, which were much admired. His camera was quite a miniature, and the stand rigid, although, when folded, it had the appearance of a substantial walking-stick—quite a curiosity in its way.

Mr. Hooper afterwards explained the mode he employed of obtaining enlarged pictures, very much in the same way as Mr. Griffiths, and exhibited some very fair specimens, but not so full of half-tone as he hoped to produce them.

A vote of thanks to Mr. Griffiths for his interesting and useful paper was carried, and also to the Chairman for presiding, which concluded the business of the evening.

Practical Instructions on Coloring Photographs.

By Alfred H. Wall.

CHAPTER VII. *(Continued.)*

PREPARATION OF THE PHOTOGRAPH.

The albumenised prints are not so frequently chosen by colourists as those on plain salted paper, because the colours adhere better, and the washes can be repeated with more safety on the latter than the former; but some exquisitely beautiful effects have been obtained on both the one and the other. The albumenised paper gives softer gradation and better detail. To assist the colourist in securing for the latter the advantages of the salted paper, Mr. Newman has recently prepared a solution which, while it answers admirably for the preparation of the prints on both papers, has the excellent quality, when used with water as a medium for your colours, of enabling you to repeat the washes without fear of their being disturbed.

Many means of preparing the print have been adopted, some using ox gall, some isinglass with two or three drops of ox gall, some a weak solution of gum. Others use parchment size, containing a very small portion of alum; and others, again, a combination of distilled vinegar, borax, and gum-arabic; but I have found no preparation to surpass that already spoken of as manufactured by Newman. In preparing the salted paper you will find it more or less absorbent, according to the method of washing and fixing adopted. Some prints will require two, or even three coats of size, and others but one, while some may be used without any preparation. In spreading the sizing solution, do it evenly and thinly, that it may not assume the appearance of a varnish, and let one coat dry thoroughly before applying a second.

THE GUIDE.

This is a second print, much darker than the first, which the colourist places beside that he is about to colour upon, as a guide to assist him in preserving the drawing and details of the photograph. It should be printed upon albumenised paper, with every scrap of detail unmistakeably secured. When the negative is of that peculiar character which requires the drapery to be sacrificed to the proper definition of the head, or the contrary, two guides should be printed, one for the head and the other for drapery.

PRACTICE.

You have taken your seat at your desk, resolved to be very patient and particularly careful, or we will suppose you have done so. The water, brushes, colours, ox gall, gum water, and palette are at hand in a clean condition for work.* The picture before you is, say the portrait of a fair person of the fair sex (you shall have a dark one of the fair sex and some others anon). I would recommend you always to colour from the life, and never, unless impossible to do, without a sitting for the colouring; as the results will always be more satisfactory, and the practice infinitely more advantageous.

Foreign Correspondence.

Paris, March 26, 1860.

At the last meeting of our Photographic Society, M. Fordos read an interesting paper *On the Employment of Salts of Gold in Photography*. He explained how necessary it was that the chlorides should be perfectly neutral, for if they contained any acid—and the commercial chlorides generally do—they decompose the hyposul-

* See the number for December 1st, 1859.

phite of soda, and cause *sulphurising* of the proofs; for the re-action of the acid of the chloride of gold upon the hyposulphite liberates hyposulphurous acid. *Sel d'or*, which is composed of hyposulphite of gold and of soda, is preferable to chloride of gold, as it does not tend in any way to produce sulphurisation; but it is less economical, inasmuch as it requires three drachms of *sel d'or* to produce the same toning effect as two drachms of chloride of gold.

M. Fordos recommends, as a substitute for chloride of gold and *sel d'or*, the double chlorides of gold and sodium, or of gold and potassium. These double chlorides contain as much gold as the commercial chlorides of gold, and may be employed in the same proportions. They are neutral, and have an invariable composition; they are also very stable, and do not attract humidity from the air; they can be kept for use in large quantities; no difficulty will be experienced in weighing them out, as they do not liquify like the chloride of gold. The preparation of these double chlorides of gold and sodium, or of gold and potassium, is not at all difficult; and it is desirable that they should immediately supersede the chloride of gold and *sel d'or* now employed for toning.

Woodward's solar camera has produced no little commotion in the photographic world. Great pains have been taken to prove that it is neither new or good: many claimants have come forward to show that in years gone by they imagined or invented something like it, but none appear to have contrived the thing itself. The discussions it has caused will doubtless lead to the production of an instrument as perfect as science can make it. M. Bertsch read an interesting communication on this subject before our Photographic Society, to which I beg to commend the attention of your readers. J. P.

Correspondence.

☞ **We are at all times willing to assist our Correspondents to the utmost of our ability, but we can only do so through the medium of the Journal. We cannot give private replies except to personal friends.**

APLANATIC LENSES.

To the Editor.

Sir,—I have waited to the present time in hope that Mr. Wilson, of Aberdeen, would, by replying to "X's" letter in your number for February 1, have relieved me of the necessity of myself replying to the subject matter of that letter.

Mr. Wilson could have told you how a hasty expression in a letter of his to the editor of a contemporary was caught at by the latter, and that he (Mr. Wilson) reluctantly, and only on the urgent solicitation of the said editor, consented to a modification of that expression being published. Mr. Wilson could also have told you that this hasty expression was induced by a query from the said editor, as to what lenses he used in taking a certain photograph having so much distortion—the question of distortion thus arising altogether with the editor, and not with himself.

Mr. Wilson could also have told you that his disappointment, as expressed (well or ill-founded), was confined to distortion, and, consequently, had no reference to fogging—Mr. Wilson limiting his statement respecting the lenses to this, viz., that he was disappointed in their working. Anything more than this is (according to Mr. Wilson's letters to myself) not from Mr. Wilson, nor with his authority.

To which, I am enabled to add (but from another source) as follows, viz.:—That the said editor has not merely expressed his opinion, but *given his "ipse dixit,"* that everyone knows, except myself, apparently, that my aplanatic lens has "*precisely the same*" *distortion as the ordinary single achromatic view lens.*

Now, I think that every one reading the article by the editor, referred to by "X," must consider it as an attempt to show that the results of a first rate photographer, using the aplanatic lens, are—foggy pictures, and with more distortion than if taken by an ordinary view lens.

That the aplanatic lens, *being a single cemented compound*, can be more liable to produce foggy pictures than any other single cemented compound, is not only grossly absurd, but, also, it comes not from Mr. Wilson. That both of these compounds are far less liable to produce foggy pictures than more complex ones, and especially than the lens or lenses known under the appellation of symmetric triplets, are facts which can no longer be disguised from those interested in such matters. That the aplanatic lens has more distortion than the ordinary view lens has been, and perhaps still is, the opinion of Mr. Wilson; but the editor before-mentioned, in craving for leave to publish that opinion, was urging for the opportunity to put before his readers (fortified by the judgment of a first-rate photographer) *that* which his aforesaid "*ipse dixit*" *declares cannot exist.*

Taking here a slightly retrospective view, the original question of the editor to Mr. Wilson was *(coming from him)* entirely superfluous. *From the kind* of distortion exhibited by the photograph, no other lens extant than either the aplanatic or the ordinary meniscus *could have been used;* and if the editor knew, in accordance with his *ipse dixit*, that *these have precisely* the same distortion, the *cui bono* of his question does not appear. I shall here mention a slightly collateral circumstance.

From Mr. Wilson's letters to me it appears that the inquiry made of him was respecting a view of *Holyrood*, and that he replied, "these views of Holyrood," &c.; whereas, in the editor's letter to myself (in which he states that he quotes from Mr. Wilson's letter, which is now before him) the quotation runs thus—"Those views of ———, where the pillars," &c. Now, the photograph enclosed to me in the same letter is *not* of *Holyrood*, but of *Melrose*. I might have supposed the substitution of the photograph of *Melrose* for that of *Holyrood* to have been accidental, but for the apparently non-accidental blank in the letter. If the distortion were equal in both photographs, there would be no reason for substitution. The view of *Melrose* was probably *not done* by the aplanatic lenses.

I now come to discuss that part of the matter in hand, which is alone generally interesting to photographers—viz., the correctness or not of Mr. Wilson's deductions respecting the distortion produced by the aplanatic lens. I would desire to preface the observations which follow by stating that I am quite convinced of his acting with perfect sincerity throughout, though not with corresponding judgment, and I here thank him for replying to my queries.

When Mr. Wilson received the lenses, now twelve months since, he expressed himself pleased with their appearance (he had seen something of the aplanatic lens before with a friend); it was ten months after, and through an adverse channel, that I first learned his "disappointment." I wrote to him, and received in reply his letter of 10th November, which states—"Indeed this" (viz., his visit to Holyrood) "was the first time I had given them a fair trial, and I have never used them since." The same letter announces his having reluctantly authorised his disappointment in the lenses *to be published.*

Of the correctness of the deductions of Mr. Wilson from this one "fair" trial I have now to speak. The trial was a comparative one; the data I take from Mr. Wilson's letters and photographs, the latter being taken with a pair of aplanatics and a pair of the ordinary view lenses, the camera being stationary. The relative foci of the two pairs of lenses, obtained from the measurement of certain definite portions of the images, proves to be as eight to ten.

Now, supposing the lenses to be of *precisely the same construction*, the distortion for a field of a given size would be inversely as the squares of the foci, or in the case before us—100 parts for the shorter focus to 64 parts for the longer. To represent this graphically I describe segments of two circles in this proportion, say of 5 and 3·2 inches radius, and draw a straight line through each segment, intersecting it at two points similarly distant in each. The diagrams so produced show by inspection the proportional distortion of the two foci of lenses used by Mr. Wilson *(supposing the lenses to be of precisely similar construction).* How far Mr. Wilson has made due allowance for this difference may be understood from his own words:—"The second pair of lenses are of slightly longer focus than yours, which may make some difference." (!)

The reason of Mr. Wilson's disappointment in the performance of the aplanatic lenses is not, however, confined to his ignoring a difference of 100 to 64 in the distortion necessarily attendant upon the difference of focal length of the two pairs of lenses. His same letter states as follows:—"When I looked at your lenses first, I thought them good; but I had them directed at rather distant objects at that time. At Holyrood, however, I found great difficulty in getting both lenses to give the *same distortion*; and, if I recollect rightly, I had to turn one of them round a little, and out of focus, before I could get that large window to lean the same way in both views. The images were something like this,* and as I turned round one of the lenses the images turned also, until I got them both to lie in one direction.† When Mr. ——— showed me his pair, I expected they would be suitable for taking such as the samples which I enclose,‡ as he said they would work with a large diaphragm. I was obliged, however, to revert to my old pair of common lenses," &c.

Need I observe, that the extraordinary kind of distortion which Mr. Wilson has here so accurately described, as well as his curing it by turning round one of the lenses, and thereby putting that view out of focus, were both imaginative on his part? I wrote to Mr. Wilson at length, showing that such phenomena were irreconcilable with the circumstances of spherical surfaces and a centred lens, and mentioning something which might have led to his error. I also begged him to send me the lenses for my personal examination and at my own expense. Mr. W. has since acknowledged that there exists neither the impossible defect in the lenses nor the possible defect in the mounting. He declines sending me the lenses for examination, and concludes by stating that he has just the same opinion of the lenses now as when he wrote to your contemporary, viz., that he was disappointed in them.

Under such a declaration, *made in the face of the acknowledged erroneous deductions of the "fair" trial*, I have thought it quite useless to pursue the question further with Mr. Wilson, and I think it better to leave it in the hands of your readers.—I am, yours, &c.,

Dublin, March 16, 1850. THOMAS GRUBB.

* Diagrams were here given of pictures leaning off from each other.
† Diagrams here given of pictures erect.
‡ Instantaneous photographs.

BLACKING BRASS MOUNTINGS.

To the Editor.

Sir,—Will you have the goodness to favour me with a formula for blacking brasswork, such as the manufacturers of philosophical instruments use for the inside coating of telescopes, lenses, &c. — one that will not offer a shining or reflecting surface.—I am, yours, &c.

March 10, 1860. RUSTIC.

[Take common spirit lacquer, such as you purchase at the varnish shops, and, after rubbing it up in a mortar with the finest lamp black, filter through calico or muslin. In using this material you must not overlook one point, viz., to make the brass-work sufficiently hot to volatilise the spirit almost immediately, otherwise the surface will be shining, instead of presenting a dead black.—Ed.]

PORTRAITS IN THE OPEN AIR.

To the Editor.

Sir,—I am a constant reader of The British Journal of Photography, from which I gather a great deal of useful information. At present I am at a loss on the following subject:—Having no glass room, or convenience for erecting one, my portraits must be taken in the open air, and, consequently, I seldom succeed in obtaining a good one. I have some idea of making a moveable screen for the sitter, after the manner of the screen we generally see carried about at the performance of Punch and Judy. I should feel much obliged by your kindly telling me, in your next Journal, whether you consider such a screen likely to answer my purpose, and, if so, what height and width it ought to be, and what kind of material you would recommend the sides to be covered with.—I am, yours, &c.

March, 1860. J. R.

[To make such a screen as you require, construct, in the first instance, a strong deal framework, consisting of a central portion with two lateral ones hinged to it. Cover the whole with oil-cloth, painted of the colour of brown paper, and as free from gloss as possible. By bringing one of the sides forward, you are enabled to throw a shadow on a part of the face, and by turning the other side back, you fix the whole arrangement, and make it firm. Probably a screen will be required above to cut off the vertical light from the head; and, if so, the apparatus may be still further strengthened by constructing this part of a deal framework, made to bolt down against the side which projects forward. Do not omit to shield the front glass of the lens from diffused light, by a funnel about a foot long, open at the end; and remember also to throw a black cloth over the camera during the exposure.

With reference to collodion, the negative collodion employed for portrait-taking in glass houses is not always the best for open-air work, the light being so much stronger, and, consequently, producing a more intense negative. A bromo-iodised collodion, such as is generally used for the Fothergill dry process, gives a very soft picture, and the proper mode of developing it is to begin with sulphate of iron, and intensify subsequently with pyrogallic acid; or, if you prefer it, pyrogallic acid may be used alone, the strength being three grains to the ounce of water, with twenty minims of glacial acetic acid. The bromo-iodised collodion will improve by keeping for a month in the iodised state.—Ed.]

ACETATE OF SILVER IN THE BATH.

To the Editor.

Sir,—I have taken photographic views, and copied engravings on plates of eleven by nine inches, and my success has been, on the whole, encouraging; but the great secret seems to me to lie in the proper constitution and management of the nitrate bath.

Mine contains about fifty ounces of solution, and was prepared about nine or twelve months ago with fused nitrate of silver (thirty grains per ounce). Some time ago it became acid, and finding the negatives inferior to what they had been, I neutralised the solution with carbonate soda, and added acetic acid. This treatment I have had occasion to repeat, but I find there is a great difficulty in keeping the plates from becoming solarised with the exposure necessary for the shadows.

What I wish to ascertain is, whether this unfavourable condition is owing to the formation of acetate of silver, and if so, how can it be corrected? The collodion I use has generally been iodised from a few weeks to three months.

I also should be very glad to learn your opinion on Mr. Thomas's suggestions, as contained in his papers in the *Journal of the Photographic Society*, and his preference for *nitric* acid.—I am, yours, &c.,

J. B. B.

[The effect of which you speak is doubtless due to acetate of silver in the bath, and it would be possible to remove this acetate by cautiously dropping in nitric acid until acetic acid had been set free. We think, however, that it might be worth your while to try, in the first instance, the effect of a developer containing *citric acid* (half the weight of the pyrogallic acid), which we have found to work well with a bath containing acetate, and, in a great measure, to remedy the solarisation. A bromo-iodised collodion, such as is used for positives, will also frequently give good negative landscapes and negative copies of pictures in a bath containing acetate.

Mr. Thomas's observations appear to us to be sound, but we are of opinion that they do not apply to all collodions; as collodion giving an intense negative will often work well in a bath faintly acid with nitric acid, but a weak collodion will not work well in such a bath. As regards oxide of silver for neutralising the bath, it is perfectly efficacious, but we find carbonate of soda to answer the same purpose: immediately on entering the bath it becomes carbonate *of silver*, and carbonate of silver acts as a neutraliser of acid, just as oxide of silver does.—Ed.]

ANSWERS TO CORRESPONDENTS.

Oxon.—A twin-lens camera is preferable.

Caustic.—We shall have much pleasure in introducing you.

Lotus.—The lime light is well adapted for the magic lanthorn.

Battley, A.—Crystallisable and glacial acetic acid are one and the same thing.

Æsop.—You are unwise to believe in such improbable advertisements.

Alcohol.—Spirits of wine will be cheaper under the new tariff.

Captain Scott.—Your *note* has reached us, but *not* the stereographs, as yet.

Boston.—By adding a solution of common salt you convert it into chloride of silver.

B. Jones.—Gum arabic produces a reddish negative when used as a preservative coating.

J. Martin.—Waxed-paper is used dry, and very excellent results may be obtained with it.

Old Hypo.—Add fresh crystals of hyposulphite of soda with every new batch of prints you put into the bath.

Archer, J.—You can obtain a daguerreotype apparatus at some of the dealers in photographic materials.

S. O.—The sediment in your developing solution is metallic silver in a state of fine division; decant the liquid.

Mellor.—There is a book on the oxymel process, published by Messrs. Chapman and Hall.

Photos.—Perhaps the lime light, or the Fitzmaurice light, will answer your purpose better.

Troy.—An ounce of nitrate of silver usually weighs 437½ grains, not 480, as you suppose.

Green.—You should have known better than to have put faith in such a palpable take-in.

S. M. G.—There is nothing new in your idea; it has been tried already and found wanting.

Watt, J.—Develop with protosulphate of iron, and afterwards strengthen with pyrogallic acid.

Duro.—Your proofs were allowed to remain too long in the toning bath: hence their cold blue colour.

Test Tube.—Your litmus paper should be kept in a bottle, covered, to avoid the action of the atmosphere.

Shotley.—The metagelatine process, as improved by Maxwell Lyte, was published in this Journal last year.

Paul.—Gelatine should not be mixed with the albumen for positive paper: it produces a very disagreeable gloss, much inferior to that obtained from pure albumen.

T. J.—If you can wait a few months, you will be able to get a copy of a new edition of the work you name.

Penelope Ann Spriggins.—Want of space compels us to postpone your communication till our next number.

Steady.—Your principle is a good one as a rule, but in this case we advise you to make an exception. Try it by all means.

Mark Haynes.—See Mr. Hughes's paper *On Toning*, in a recent number, or Mr. Maxwell Lyte's formula in our last volume.

J. M.—If you apply to the author of the paper he will doubtless forward the instrument to you, and we think that you may depend upon its answering the desired object.

F. S. W.—You will find exactly what you need in the last number but one of The British Journal of Photography, page 62.

H. N. King.—We have not forgotten you, but have really not had time to do what you require; our labour is constantly increasing. We hope to try it in about a fortnight's time.

Cantankerous.—You have shot at the wrong mark—*we* retired from the council of the society more than *twelve months* back (not agreeing with the policy then pursued), so that we are in no way responsible for the acts of which you complain.

H. A.—Plain or waxed-paper negatives may be intensified by coating them with a dilute developing solution, silver and gallic acid. The operation must be performed in the dark, and with great cleanliness.

Rt. M'L.—See an article in our last number on "Perspective and Distortion," also our leader in the same number, when you will be in possession of our opinion on the subject alluded to. On the other point you may consult our number for the 15th Dec., 1859.

Nil Desperandum.—If carefully prepared, kept in the dark, and protected from vapours of all kinds, you may generally calculate on them for a month. Whether you are to prefer the four-drachm washing, or the unlimited washing, will depend upon the state of the collodion—try a plate of each before starting.

T. L.—We cannot detect any defect in the print sent, excepting two little spots, which appear to be due to an impurity of some kind having touched the paper. The larger red spots to which you allude may perhaps be caused by your allowing the pictures to lie too closely together, so that the bath cannot act evenly.

Roberts.—If you suspect the spots to be due to floating particles in the [illegible], remedy them by a more careful filtration; but has it not occurred to you that possibly your apparatus may be a little stiff and out of order? at all events you can try the effect of cleaning the slide very thoroughly. We imagine that Mr Llewelyn adheres as a rule, to the oxymel process as he first described it, adopting the modification only when the collodion is unsuitable.

T. K.—See answer to J. M. We are of opinion that a careful washing will do more to secure the permanence of your prints than the application of a heated iron after drying, the effect of which would be difficult to explain satisfactorily.—Question 2. We do not recommend the general adoption of development by salts of iron: no one plan of development will answer equally well at all times. Use the salts of iron when, from any cause, you obtain too much intensity of negative, and the pyrogallic acid when the image is pale and flat. A proper strength for the iron developer is about ten grains to the ounce, with twenty minims of glacial acetic acid; and it will depend much upon the state of the collodion and bath whether pyrogallic acid should be employed subsequently.

Received.—J. G., W. B. C., J. B. B., Amateur. Will all receive attention in our next.

⁂ A pressure of matter compels us to leave over several articles in type, amongst which are Mr. Forrest's paper "On Glass," M. Bertsch's paper "On the Enlarging of Positive Proofs," "Letter" of Israel Holdsworth, &c., &c.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 116, Vol. VII.—APRIL 16, 1860.

A matter of no small interest has been recently placed before our readers with reference to certain experiments bearing upon the question of the proper fixation of positive paper proofs. We allude to those reported in our impressions of the 15th ultimo and the 1st instant, by MM. Davanne and Girard at page 82, by Mr. Hardwich at pages 93 and 94, and by Mr. Dawson at page 100; and we recommend all who regard the permanence of photographs upon paper as a matter of importance (that is, every photographer worthy of the name) to make himself thoroughly acquainted with the whole of the bearings of the subject. A careful re-perusal of these articles consecutively will well repay the trouble; for not only is the subject matter of vital interest, but it is not such as readily to be apprehended by the casual reader. We propose therefore to attempt a slight analysis of the propositions arrayed on both sides of the question.

MM. Davanne and Girard assert that a solution of hyposulphite of soda of the strength of ten per cent. becomes *saturated* with the double hyposulphite of silver and soda, as soon as the former has dissolved thirty-six grains of chloride of silver in the quantity of liquid containing twenty-five drachms of new hyposulphite of soda. They state also the fact that this so-called saturated solution is capable of dissolving a much larger quantity of chloride of silver; but that, in order that it may do so, decomposition of the alleged saturated solution, as well as of the chloride of silver, must take place, more of the double salt being formed, which is then precipitated from the quasi super-saturated solution, subsequently to which further decomposition is alleged to ensue with the formation of sulphate of soda, sulphurous acid, and sulphur. These gentlemen also say:—

> The sulphur thus formed will be deposited on the proof, side by side with the sulphide of silver, so that not only a part of the silver covering the proof will be sulphurated on leaving the bath, but it will also carry off a second quantity of sulphur, which, little by little, will sulphurate the unattacked silver and alter the proof, and consequently make it undergo a more considerable sulphuration.

On this point we offer a suggestion. If any free sulphur be formed it ought to be removable by immersing the print in bisulphide of carbon, and the sulphur subsequently recovered on evaporating the solvent. We quote another assertion of MM. Davanne and Girard, viz.:—

> If we take a quart of a solution of hyposulphite of soda, of the strength of 10 per 100, and stir into it forty grains of freshly-precipitated chloride of silver, the latter will be dissolved, and form the normally-saturated solution spoken of above. If to this saturated solution we add a second and then a third quantity of chloride of silver, equal to forty grains, these quantities will successively dissolve; but the solution will become unstable, and soon deposit, not the double white salt, but free hyposulphite of silver, which is immediately decomposed.

Now, in direct opposition to this assertion, we find from the experiments of Mr. Dawson, as reported at page 100, that ninety-six grains of hyposulphite of soda dissolved in half an ounce of water took up twenty-five grains of chloride of silver during the first day's experiments, and that, being left in repose for twenty-four hours, *no precipitate was formed*, nor did the litmus paper kept continually in the liquid exhibit *any signs of acidity.*

Again, turning to Mr. Hardwich's researches, we find that the only deposit produced was in the form of crystals of a double salt of hyposulphite of soda and silver, containing one atom of each base, that *not* being identical with the double salted treated of by MM. Davanne and Girard, which is the compound consisting of one atom of the silver salt to two atoms of the corresponding soda salt, and which Mr. Hardwich states to be *very soluble in water*, consequently, except the solution be considerably concentrated, not likely to crystallise very readily. No deposit of hyposulphite of silver, or of any other kind, was formed in either solution of Mr. Hardwich's, and even at the expiration of a week both remained clear and colourless: in that containing the chloride of silver equal to half the weight of hyposulphite of soda alone, sparkling crystals (not decomposed) were found.

In connexion with this subject we have been not a little amused at an editorial comment in the pages of a contemporary, after a report of the meeting of the North London Photographic Association, at which Mr. Dawson related the account of his experiments, which were consequently before the editor; and though those of Mr. Hardwich were not, the fact that an eminent chemist had completely corroborated Mr. Dawson's results was in evidence, for we find it recorded in the same page as the comment to which we adverted. This comment is as follows:—

> MM. Davanne and Girard's statement appears to have been misunderstood. Their assertion is simply this—a solution of hypo, of the strength of ten per cent., will dissolve only about one grain to the ounce before becoming saturated with hyposulphite of silver and soda. When so saturated, hyposulphite of silver is precipitated and immediately decomposed into sulphur and sulphide of silver, and sulphurises the proofs.

The worthy editor does not appear to perceive that the assertion so far from having been *misunderstood* was simply *confuted*—a widely different affair.

It is not unfrequently that we have to point out that alleged photographic novelties do not always consist in anything new. We are fully aware that this is a somewhat ungracious task; but we are constrained to select one of two evils—either we must be silent and run the risk of being twitted for our own want of memory by some correspondent, and at the same time commit an act of ingratitude towards the original introducer of something useful, or we must take the course which we constantly do, and brave the ire of the second in the field.

At the March meeting of the French Photographic Society, M. Fordos read an article *On the Preparation and Use of the Double Chloride of Gold and Sodium for Toning Paper Positives*, alluding to this salt as if it were but very recently brought into use for this purpose, though he stated that he had, in conjunction with M. Gelis, manufactured the article as long since as 1843, a period at which it was of course not applied for the purpose now indicated. We think it is, however, rather late in the day to regard as a novelty what has been in pretty constant use, in this country at least, for the last five or six years: first by the "printing

committee" in this country in 1854, at the suggestion of Dr. Percy, in order to avoid the inconveniences arising from the use of an acid salt like the terchlorides of gold; in short, it is the basis of what is known as Maxwell Lyte's gold toning bath, and has been still longer in use for extemporising a *sel d'or* bath,—which latter, by the way, M. Fordos still regards as the best agent for toning, on the alleged ground that sulphurisation is altogether avoided by its use. In this opinion we consider he is altogether mistaken; for we believe that the toning is effected by the sulphur attacking the silver, and thus causing the deposit of the gold in the metallic form.

In our last we puplished the report of a meeting of the Blackheath Photographic Society, at which matters of unusual importance were brought forward. In the first place, the paper by Mr. C. J. Busk, *On the Reproduction of Engravings, Writing, &c.*, not only presents to our notice some interesting and useful results, but tends to indicate the possible source of M. Nièpce de Saint Victor's supposition of having discovered some hitherto unknown action of light.

The essence of Mr. Busk's article appears to be as follows, viz.:—Paper steeped in an acid of some kind (organic preferable), dried, and then washed with a solution of nitrate of silver and again dried, is brought into contact with the object to be copied, and retained there for an indefinite time (from five minutes to nine hours, half an hour being considered enough). On subsequently exposing the sensitive paper to sunlight a negative impression is developed, which becomes fixed by thoroughly washing with plain water. The following appears to be an approved formula for preparing the paper:—Mix one ounce of glacial acetic acid with three ounces of water: in this steep the paper and hang it up to dry. Wash on both sides with solution of nitrate of silver sixty grains, water seven drachms, glacial acetic acid one drachm: dry.

It is expressly stated that it is *not* necessary that the writing, engraving, &c., to be copied should have been exposed to light, and that the prepared paper, after removal from contact with the original, may be kept for some days before development by sunshine if preserved between sheets of white paper.

Here is a wide field open for experiment. We should much like to know more about this interesting phenomenon, for it seems possible that a great assistance to the multiplication of copies in bad weather may be within our reach. Nothing appears to have been said in discussion about half-tone; in fact, for aught we are informed, the paper did not elicit any discussion at all. This was very likely owing to the next matter of stirring interest which was before the meeting—a strong protest by Mr. Heisch against the Report of the Collodion Committee, recently published by the Photographic Society; and Mr. Heisch's protest was subsequently unanimously adopted as expressing the opinion of the Blackheath Society.

With regard to the "Report" itself, we pointed out some of its failings in a previous number; but we think that Mr. Heisch has been scarcely just to Mr. Hardwich in his observations, as, although he does not expressly state as much, he seems to imply that Mr. Hardwich is commercially interested in the question. Now, in point of fact, this is not the case. Mr. Hardwich has no pecuniary interest in the matter; on the contrary, he has made a great sacrifice in entirely abandoning the manufacture of a very remunerative article, and by unreservedly publishing the result of his labour and experience for the general benefit of photographers, and this without fee or reward of any kind. We have the best authority for the correctness of this assertion.

There were so many subjects of discussion at the last meeting of the Photographic Society (London) that it was very difficult to get through them all, and was only accomplished by an unusually protracted sitting: in fact, there was matter enough for three ordinary meetings. The report of what took place will be found in the usual column, but we have a comment or two to make thereon.

During the discussion of the subject of "burning in" photographs upon glass, M. Joubert exhibited two specimens of his own production by a new process, for which we understood him to state that he proposed procuring a patent. Whatever may be the process employed, the result is certainly most beautiful. One specimen was the portrait of an elderly lady in a black dress and white cap, which displayed the most delicate gradation of tone between both extremes, and with exquisite softness and finish. Whether viewed as a transparency or with a background of white paper the effect is equally satisfactory.

On the discussion upon the panoramic lens the very general animosity displayed towards the inventor can only be accounted for by the injudicious manner in which he has not only sung its praises, but endeavoured also to pour contempt upon all who should not regard it with as favourable an eye as he does himself. It should be borne in mind, however, that there is one marked difference between the cases of the orthographic and the panoramic lenses: the former was originally introduced with plenty of laudation, but no description of its construction; while with the latter no concealment of the principle of construction was attempted, although it was accompanied by even more praise than its predecessor. It was remarked by one speaker that "this lens was a mere attempt to copy the human eye." If this expression were intended by way of detraction, we think it was very injudiciously chosen. We cannot regard such an attempt as objectionable. Although we consider the result as unsuccessful beyond a very limited extent, it is not a failure of which any one would need to feel ashamed; and we feel convinced that but for the absurd claims set up for qualities which it does not possess, more justice would have been done to those which it has, as well as to the ingenuity which we feel constrained to admit has been shown in its design.

SUGGESTIONS FOR A HELIOGRAPH.

By W. Hislop, F.R.A.S.

The near approach of the great solar eclipse of July, 1860, induces me to offer a few suggestions for the construction of a new heliograph for the purpose of obtaining photographic pictures of the sun's disc. The attention of astronomers has been for some time directed to the importance of obtaining accurate delineations of the Protean changes which take place upon the surface of our great luminary, in order, if possible, to ascertain the laws which govern them. At the present moment the subject acquires greater interest from the possibility that what has often been mistaken for a spot being nothing more nor less than a planet, new to science, and interior to all the rest. In the case of a solar eclipse, also, it is extremely desirable to obtain a record which shall be more trustworthy than the observations of individuals, who may differ in their visual powers, and in their mental ability to note correctly what they really see. Some important scientific questions depend for satisfactory solution on data which photography seems alone capable of obtaining with precision.

A large heliograph has already been constructed for the Kew Observatory, consisting in fact of a telescope with an aperture of six inches (if my memory serve me aright), and producing an image of the sun's disc about four inches in diameter. The quantity of light and the large aperture employed render it difficult to expose the plate a sufficiently short space of time, and recourse has been had to retarding the sensitiveness of the plates by various means well-known to photographers. It is proposed, about the time of the eclipse, to transport this instrument to Spain (across which country the path of totality passes in a diagonal direction), in order to register the phenomenon in its various phases. This heliograph in consequence of its size is cumbersome, and also expensive, and, as I have just observed, is nothing but a telescope with various adjuncts to adapt it to its particular work.

Want of time has hitherto prevented me from making more than a few preliminary experiments towards perfecting the instrument, the construction of which I now suggest.

I propose to take a view lens of about 26 inches focus, and of a diameter sufficient to ensure accuracy in the figure. This should be furnished, at the proper distance in front, with a series of stops

from say 1-16th of an inch to the larger size, at which the lens will work without sensible spherical aberration. These apertures should be so arranged as to be readily changed, and may be either holes pierced in a plate of brass sliding in front of the lens, or be arranged in a circular disc, turning on a centre, similar to the diaphragm of a microscope. The lens so fitted should be fixed at the end of a telescope tube of the proper length, and the image of the object, instead of being received upon a screen, or impressed upon a sensitised plate, should be received by another photographic lens, adjustible at the proper distance to magnify the image. The best lens for the latter object would probably be one on the orthographic principle, which construction would also increase the means of correction in combination with the front lens, so as to obtain the utmost amount of accuracy of picture.

In the rear of the back or enlarging lens should be the arrangement for holding the focussing screen and dark frame, which arrangement should be capable of moving backwards and forwards, so as to get a smaller or larger picture.

It would be convenient at times to impress more than one image upon a single plate. For this purpose, the dark frame should be of an oblong shape, similar to that of a stereoscopic camera. One picture having been impressed the proper time, could then be passed forward, and another part of the plate brought into position. For rapid work, such as would be necessary in registering an eclipse, the dark frames might be passed through the groove, and so made to succeed each other rapidly, being prepared by one assistant and received and developed by another. It is probable, however, that dry plates would be found most convenient when the observer has no assistant.

By the arrangement I have thus described, instead of retarding the sensitiveness of the plate by chemical means as is now done, we have the power mechanically of diminishing the light, and at the same time arriving at our results by a shorter path. Thus we may diminish the light and also spherical aberration by using a smaller stop, while, with the aperture remaining the same, we may enlarge the image at the point of impression, and so reduce the energy of the light by diffusion. At present the image obtained on the negative plate is afterwards enlarged by optical means, thus making two operations: by my proposed arrangement the image would be obtained of an increased size by one operation.

The exposure being comparatively instantaneous, no mechanism would be necessary for keeping the instrument moving with the sun; and, as an illustration of the rapidity of action, I may mention that with a lens of eighteen inches focus, producing an image of the sun's disc rather less than a quarter of an inch in diameter, and having a stop of one-sixteenth of an inch, it was difficult to expose for a sufficiently short time to avoid solarisation, even with an acid bath.

An instrument of this kind can only be constructed by those who undertand some little of astronomy, optics, and photography; and as many of your readers have the mechanical facilities for effecting the corrections required, I take the liberty of forwarding the above suggestions for insertion in your Journal.

ON PANORAMIC AND PLANE PERSPECTIVE.

By Thomas Sutton.

[Read at the Meeting of the London Photographic Society, 3rd April, 1860.]

In plane perspective, when a wide field of view is included, the objects at the sides of the picture appear misshapen and disproportionately large. They appear misshapen because the pyramids of visual rays of which the eye is the vertex are cut by a plane inclined to those rays at an angle of *great* obliquity; and they appear disproportionately large for a reason which will be explained by the following illustration:—
